PUBLICATION RECORD

EFFECTIVE DATE	REVISION NUMBER	DESCRIPTION
04/20/2004	00	New technical basis document for the Nevada Test Site– Occupational Environmental Dose. First approved issue. Initiated by Eugene M. Rollins.
12/08/2006	00 PC-1	<p>Approved page change revision as a result of biennial review. Adds acronyms and abbreviations on pages 4 and 5. Updates required language on page 6 in the Introduction. Adds Purpose and Scope sections on page 7. Added instructions to dose reconstructors on pages 44 and 45 in Section 4.5. As a result of formal internal review, deletes Section 4.5.2 from page 45. Completes references on page 47. This revision results in no change to the assigned dose and no PER is required. Training required: As determined by the Task Manager. Initiated by Eugene M. Rollins. Approval:</p> <p><u>Signature on File</u> 12/05/2006 Eugene M. Rollins, Document Owner</p> <p><u>Signature on File</u> 10/24/2006 John M. Byrne, Task 3 Manager</p> <p><u>Signature on File</u> 10/24/2006 Edward F. Maher, Task 5 Manager</p> <p><u>Signature on File</u> 11/15/2006 Kate Kimpan, Project Director</p> <p><u>Brant A. Ulsh Signature on File for</u> 12/08/2006 James W. Neaton, Associate Director for Science</p>
05/27/2008	01	<p>Approved revision initiated to apply only to post 1962 employment periods and all covered employees including those identified by job classification as a drillback operator prior to 1965. Also applies to covered employees involved with any of the 10 underground tests that resulted in unexpected release of radioactive materials. Revised Table 4.2.1.2.2.-2 (new Table 4-3) to reflect 2,000 hr/yr and 2400 m³/yr breathing rate. Deleted Tables 4.2.1.2.2-3 and 4.2.1.2.2-4. Deleted Sections 4.2.1.2.3 and 4.2.1.2.4. Added Sections 4.2.1.2.3 and 4.1.2.4 to introduce revised method for assigning environmental ambient inhalation intakes. Replaced Section 4.2.2 with ambient ingestion intake section. Revised Section 4.4 to include dose from radon and other alpha and beta emitting radionuclides and to include discussion of radon exposure in Gravel Gerties. Added Section 4.4.3. Revised Section 4.4.4, Table 4.21 to increase radon WLM for G-Tunnel prior to 1984 and to maximize radon exposures for unidentified work locations. Added discussion of radon in Gravel Gerties. Added Section 4.4.5 to provide method for assigning inhalation and ingestion intakes for underground workers. Added Section 4.5.2 to provide instructions to dose reconstructors for assigning inhalation and ingestion ambient environmental intakes for all workers at the NTS. Occupational environmental dose will increase for all claims not previously worked using ORAUT-OTIB-0018 or ORAUT-OTIB-0002. Also, cases of lung, ET1, and ET2 will need to be re-evaluated for increased radon exposures. Attachments A and B (formerly Rollins 2007, SRDB Ref</p>

EFFECTIVE DATE	REVISION NUMBER	DESCRIPTION
		<p>ID: 37805) were added to support the changes discussed in Section A.6.0 which included enriching the near-field environment with refractory elements. The 01-C version only added refractory elements back to the depleted refractory near-field environment given by the Hicks data (i.e., multiplied the Hicks refractory values by 2). The 01-D version enriched the near-field refractory environment by multiplying the Hicks refractory values by 4. Assumption of the enriched refractory near-field environment resulted in larger fission and activation product inhalation and ingestion correction factors (Tables 4-8 and 4-12) and increased number of affected organs and the resultant doses (Tables 4-9 and 4-14). Incorporates formal internal and NIOSH review comments. Constitutes a total rewrite of the document. Training required: As determined by the Task Manager. Initiated by Eugene M. Rollins.</p>

4.1 INTRODUCTION

Technical basis documents and site profile documents are not official determinations made by the National Institute for Occupational Safety and Health (NIOSH) but are rather general working documents that provide historic background information and guidance to assist in the preparation of dose reconstructions at particular sites or categories of sites. They will be revised in the event additional relevant information is obtained about the affected site(s). These documents may be used to assist NIOSH staff in the completion of the individual work required for each dose reconstruction.

In this document the word “facility” is used as a general term for an area, building, or group of buildings that served a specific purpose at a site. It does not necessarily connote an “atomic weapons employer facility” or a “Department of Energy [DOE] facility” as defined in the Energy Employees Occupational Illness Compensation Program Act [EEOICPA; 42 U.S.C. § 7384l(5) and (12)]. EEOICPA defines a DOE facility as “any building, structure, or premise, including the grounds upon which such building, structure, or premise is located ... in which operations are, or have been, conducted by, or on behalf of, the Department of Energy (except for buildings, structures, premises, grounds, or operations ... pertaining to the Naval Nuclear Propulsion Program)” [42 U.S.C. § 7384l(12)]. Accordingly, except for the exclusion for the Naval Nuclear Propulsion Program noted above, any facility that performs or performed DOE operations of any nature whatsoever is a DOE facility encompassed by EEOICPA.

For employees of DOE or its contractors with cancer, the DOE facility definition only determines eligibility for a dose reconstruction, which is a prerequisite to a compensation decision (except for members of the Special Exposure Cohort). The compensation decision for cancer claimants is based on a section of the statute entitled “Exposure in the Performance of Duty.” That provision [42 U.S.C. § 7384n(b)] says that an individual with cancer “shall be determined to have sustained that cancer in the performance of duty for purposes of the compensation program if, and only if, the cancer ... was at least as likely as not related to employment at the facility [where the employee worked], as determined in accordance with the POC [probability of causation¹] guidelines established under subsection (c) ...” [42 U.S.C. § 7384n(b)]. Neither the statute nor the probability of causation guidelines (nor the dose reconstruction regulation, 42 C.F.R. Pt. 82) define “performance of duty” for DOE employees with a covered cancer or restrict the “duty” to nuclear weapons work (NIOSH 2007).

The statute also includes a definition of a DOE facility that excludes “buildings, structures, premises, grounds, or operations covered by Executive Order No. 12344, dated February 1, 1982 (42 U.S.C. 7158 note), pertaining to the Naval Nuclear Propulsion Program” [42 U.S.C. § 7384l(12)]. While this definition excludes Naval Nuclear Propulsion Facilities from being covered under the Act, the section of EEOICPA that deals with the compensation decision for covered employees with cancer [i.e., 42 U.S.C. § 7384n(b), entitled “Exposure in the Performance of Duty”] does not contain such an exclusion. Therefore, the statute requires NIOSH to include all occupationally-derived radiation exposures at covered facilities in its dose reconstructions for employees at DOE facilities, including radiation exposures related to the Naval Nuclear Propulsion Program. As a result, all internal and external occupational radiation exposures are considered valid for inclusion in a dose reconstruction. No efforts are made to determine the eligibility of any fraction of total measured exposure for inclusion in dose reconstruction. NIOSH, however, does not consider the following exposures to be occupationally derived (NIOSH 2007):

- Background radiation, including radiation from naturally occurring radon present in conventional structures
- Radiation from X-rays received in the diagnosis of injuries or illnesses or for therapeutic reasons

¹ The U.S. Department of Labor (DOL) is ultimately responsible under the EEOICPA for determining the POC.

4.1.1 Purpose

This technical basis document (TBD) discusses occupational environmental dose. Occupational environmental dose is the dose individuals received at the Nevada Test Site (NTS or Test Site) while outside operational facilities but on the site during work activities. These doses can be internal or external depending on the characteristics of the individual radionuclides. While inhalation of most radionuclides would cause a dose to various organs in the body, noble gases would primarily cause only an external dose because these inert radionuclides are not readily absorbed by the body. However, inhalation of radon will result in dose to the lungs and respiratory airways due to the subsequent deposition and decay of daughter products. Occupational environmental dose would be received by workers in both the aboveground and the underground working environments.

With the cessation of atmospheric testing at NTS in 1962, the greatest potential for environmental intakes of radioactive material in the aboveground environment results from the inhalation of radioactive particles that were resuspended from NTS soils into the atmosphere and from ingestion of soils that were previously contaminated by atmospheric nuclear weapons tests, reactor tests, and safety tests. The potential inhalation intakes can be estimated from air sampling data provided in the NTS annual environmental reports (see the Environmental Reports list in the References section) coupled with extensive soil contamination data gathered between 1983 and 1991 (McArthur 1983, 1985, 1987, 1988, 1989, 1991). Because the air monitoring data was limited to gross alpha and beta measurements, tritium, and isotopes of plutonium (e.g., ^{238}Pu , ^{239}Pu , ^{240}Pu), inhalation intakes of other relatively long-lived radionuclides that have been identified in the NTS soils (e.g., ^{241}Am , ^{60}Co , ^{137}Cs , ^{90}Sr , ^{152}Eu , ^{154}Eu , ^{155}Eu) are scaled to those of plutonium based on their relative abundance in the NTS soils. Ingestion intakes can also be estimated by assuming consumption of the contaminated NTS soils. To ensure that both inhalation and ingestion intakes are not underestimated, the relative abundances of the long-lived radionuclides identified in the NTS soils determined from the 1991 soil contamination data (McArthur 1991) were decay-corrected back to 1963. In addition, to ensure that intakes and resultant doses are not underestimated, correction factors are developed to account for potential exposures to short-lived fission and activation products based on test-specific data provided by Hicks (1981a,b,c,d). In addition, a correction factor is developed for inhalation intakes that accounts for the phenomenon of early resuspension (Anspaugh 2002).

4.1.2 Scope

Section 4.2 discusses internal doses to aboveground workers from onsite releases to the air and resuspension of radioactive materials in soil, as well as from ingestion of contaminated soils. Section 4.3 describes external doses to workers from ambient radiation and releases of radioactive noble gases into air. Section 4.4 discusses internal dose to underground workers from inhalation of ambient concentrations of radioactive materials in the air, ingestion of contaminated materials, and from exposure to radon. Section 4.5 provides instructions to dose reconstructors for assignment of environmental intakes. Section 4.6 presents attributions and annotations, which are indicated by bracketed callouts and used to identify the source, justification, or clarification of the associated information.

4.2 INTERNAL INHALATION AND INGESTION DOSE TO ABOVEGROUND WORKERS

Section 4.2.1 discusses the internal dose for workers outside the facilities, as determined from air concentrations resulting from ground-level releases. Section 4.2.2 discusses the internal dose from resuspension of radioactive materials in the soil.

4.2.1 Onsite Releases to Air

4.2.1.1 Source Description

4.2.1.1.1 Weapons Testing

NTS has been the primary location for the testing of nuclear explosives in the continental United States since 1951. Test programs have included atmospheric testing in the 1950s and early 1960s, earth-cratering experiments, and open-air nuclear reactor and rocket engine testing. Since the mid-1960s, testing of nuclear devices has occurred underground in drilled vertical holes or in mined tunnels. No nuclear tests have been conducted since September 1992 (Black 1995).

In all, more than 900 nuclear tests have taken place at the Test Site as part of these programs. One result of these tests is that the surface soils in many parts of NTS contain measurable amounts of several long-lived radionuclides. Almost all of the more than 100 aboveground tests contaminated the soil near ground zero. In addition, several underground tests were cratering experiments that threw radioactive rock and soil hundreds of feet, and some deeper underground tests vented radioactive material to the surface. A few safety tests, in which a nuclear device was destroyed by conventional explosives, scattered plutonium (and in some cases uranium) over the nearby ground. Further, there was fallout of radioactive debris from many tests over the northern and eastern parts of the Test Site (McArthur 1991).

Radiation levels at NTS have been monitored regularly, and safety officials have identified and fenced off areas where the soil is heavily contaminated. In many other areas, radionuclide levels are not high enough to warrant closing the area, but they are still above background.

Atmospheric weapon and safety tests from 1951 and 1963 resulted in the release of approximately 1.2×10^{10} Ci to the atmosphere (DOE 1996). Much of this activity was from relatively short-lived radionuclides that decayed in a matter of days or weeks. The volatile radionuclides (such as radioiodines, noble gases, and tritium) were diluted in the atmosphere and transported off the site. However, much of the nonvolatile, long-lived radionuclides settled back into the soils at various locations at NTS (see Table 4-10 in Section 4.2.2). These contaminated soils continue to represent a potential inhalation pathway to workers from resuspension of soils by wind and such mechanical activities as cleanup and remediation (McArthur 1991).

In 1963, nuclear weapons testing was moved underground to prevent the release of radionuclides to the atmosphere and achieve containment. Releases of radioactive material following an underground test are generally categorized with terms that describe both the volume of material released and the conditions of the release (DOE 1996):

- *Containment Failures:* Containment failures are unintentional releases of radioactive matter to the atmosphere due to failure of the containment system. A prompt massive release, or one that occurs soon after a test, is a venting.
- *Late-Time Seeps:* Late-time seeps are small releases that occur days or weeks after a test when gases diffuse through pore spaces in the overlying rock and are drawn to the surface by decreases in atmospheric pressure.
- *Controlled Tunnel Purging:* A controlled tunnel purge is an intentional release to allow either recovery of experimental data and equipment or reuse of part of the tunnel system.
- *Operational Release:* Operational releases are small consequential releases that occur when core or gas samples are collected, or when a drillback hole is sealed.

At the present time, processing of radioactive materials at NTS includes only laboratory analyses. Handling of these materials includes only the transport and storage of nuclear explosive devices and the operation of a radioactive waste management site for low-level radioactive and mixed wastes. Monitoring and evaluation of the various activities indicate that the potential sources of onsite radiation exposure are releases from the following sources (Black 1995):

- Tritiated water vapor (HTO) from drainage containment ponds for E Tunnel in Area 12
- Onsite radioanalytical laboratories
- Area 3 and 5 waste facilities
- Other diffuse sources

The following sections describe effluent sources at NTS from information in Black (1995).

4.2.1.1.2 Ground Seepage of Noble Gases

Ground seepage can be enhanced when changes in ambient pressure pump small amounts of noble gases up through the overburden and into the atmosphere from the cavity that is created by a nuclear test. This process, sometimes referred to as *atmospheric pumping*, creates a diffuse source of radiological effluents. These area sources are rare and therefore not routinely monitored. The phenomenon is usually restricted to tests conducted in the Pahute Mesa region of NTS. These seepages are from nuclear tests before 1993.

4.2.1.1.3 Tunnel Operations

Nuclear tests occurred in mined tunnel complexes in the Rainier Mesa region. Because some tunnels were sealed in the mid-1990s, currently small amounts of contaminated water continue to drain from only one tunnel (Section 4.2.1.1.4).

4.2.1.1.4 Containment Ponds

Water contaminated with radionuclides seeps from the tunnels in Area 12 and collects in containment ponds where some evaporates and some seeps into the soil. The only radiological contaminant that produces a measurable air emission from evaporation of the water is tritium (^3H) in the form of HTO.

4.2.1.1.5 Drillbacks

Following underground nuclear tests, core samples have been taken from the cavity that was formed by the nuclear detonation for analysis and diagnosis. This core sampling is accomplished by drilling into the area of interest and recovering samples using special equipment. Radioactive material can escape to the atmosphere during these operations.

4.2.1.1.6 Laboratories

The Reynolds Electrical & Engineering Company (REECo) conducted radiological analyses in Building 650, and Los Alamos National Laboratory (LANL) conducted similar analyses in Building 701 at Mercury. Because these facilities have processed primarily environmental samples, very little radioactivity has passed through them. However, there was potential for some radionuclides to be discharged to the atmosphere through the hood ventilation system during sample processing, particularly of spiked samples or from loss of radioactive standards that contained heavy water, radioiodines, or noble gases.

4.2.1.1.7 Radioactive Waste Management Sites

Areas 3 and 5 contain sites for the disposal of low-level radioactive waste, and Area 5 contains sites for storage of transuranic and mixed transuranic wastes, as well as the Greater Confinement Disposal Test Unit and 12 accompanying boreholes (only a few contain waste). Disposal occurs in pits and trenches; concrete pads provide temporary storage of certain wastes. Area 5 is for packaged waste disposal only. The Waste Examination Facility (WEF) houses a glovebox with high-efficiency particulate air filtration that is used to examine and repack transuranic (TRU) waste drums. No contamination has been released from glovebox operations to the environment. The drums, which have been sent to NTS from Lawrence Livermore National Laboratory (LLNL) in past years, are stored inside the TRU Pad Cover Building. Repacked drums will be sent to the Waste Isolation Pilot Plant. The facility is a diffuse source of radiological effluents. The only radioactive effluent that has been detected by the various types of samplers around the site is HTO in atmospheric moisture. The Area 3 low-level waste site is in a location where surface soil has been contaminated by deposited plutonium, and resuspension of this soil by wind and vehicular activity has resulted in detection of above-background levels of plutonium in nearby air samples.

4.2.1.2 Atmospheric Radionuclide Concentrations

In 1964, REECo established an environmental surveillance program at NTS that was designed to measure radiological conditions throughout the site without regard to nuclear tests (Gloria and Brown 1964a). That is, the collected data was not to relate to specific tests but to general conditions of radiation. The short-term objective of the program was to minimize casual personnel exposure to radiation by locating and identifying localized radiological environmental conditions by type and quantity of contamination. The long-range objective of the program was to establish baseline environmental data that could provide a reference for comparison with subsequent test activities and radiation measurements (Gloria and Brown 1964a).

The initial surveillance program included, over time, 12 permanent air-sampling stations in the most populated areas at NTS. The air samplers were low-volume Filter Queen samplers with 8- by 10-in. (Gelman Type E) glass-fiber filter papers. Operating times were determined by integrated electric timers with flow rates from calibrated rotometers. Typical flow rates varied from 3 to 6 ft³/min; samples were collected weekly (Gloria and Brown 1964b).

After the first reporting period (June 1964), positive-displacement Gast pumps, which were equipped with in-line total volume gas meters, replaced the Filter Queen samplers. In May and June of 1965, the 8- by 10-in. Gelman filters were replaced with a new sampler that used 4-in.-diameter Whatman #41 filter paper (Lewis, Gloria, and Aoki 1965). The sampling rate of these samplers was about 3 ft³/min. Therefore, the total volume of sampled air in a 7-day period was about 1×10^3 m³. During this period, the number of sampling stations increased to 13 and caustic scrubbers were added for the detection of radioiodines.

Early particulate samples were typically analyzed only for gross alpha and gross beta. However, if gross beta concentrations exceeded 1×10^{-5} $\mu\text{Ci}/\text{m}^3$, researchers conducted an analysis for ²²⁷Ac (the most hazardous beta emitter present). Because no historical evidence exists that ²²⁷Ac has been detected in air or soil samples, the assumption that unidentified beta emitters were ²²⁷Ac would be unreasonable and inappropriate. Therefore, for purposes of dose reconstruction, ⁹⁰Sr is assumed to be the unidentified beta-emitting radionuclide with the highest internal dose impact (see Section 4.2.1.2.4 for details).

Environmental samples were analyzed for gross alpha and beta radioactivity by gas proportional counting. Air samples were analyzed with a Nuclear Chicago ULTRASCALER system with a 9- by 10-in. detection chamber to accommodate the 8- by 10-in. filters. All other samples were

analyzed with a Beckman WIDEBETA system equipped with an automatic sample changer. This counting equipment and protocol allowed lower detection limits of about 2.9×10^{-9} and 1.6×10^{-8} $\mu\text{Ci}/\text{m}^3$ for gross alpha and gross beta, respectively (Lewis, Glora, and Aoki 1965). By 1978, the lower detection limit for gross beta counting had been reduced to 1×10^{-10} $\mu\text{Ci}/\text{m}^3$ (Lewis, Glora, and Aoki 1965).

Gross gamma screening was typically performed on samples that were prepared for gross beta counting. The screening was performed using a 5- by 5-in. NaI(Tl) detector that was coupled to a single-channel analyzer. Any samples that showed elevated gamma readings were sent to a multichannel analyzer for radionuclide identification (Lewis, Glora, and Aoki 1965). In the early 1970s, gamma spectroscopy was performed using germanium-lithium [Ge(Li)] detectors and 2,000-channel analyzers with a lower detection limit of 5×10^{-9} $\mu\text{Ci}/\text{m}^3$ (REECO 1978a). After cessation of atmospheric testing at NTS in 1963, fission products were frequently measured in the atmosphere but were typically correlated with foreign atmospheric weapons testing (see Section 4.2.1.2.4).

In 1971, weekly air samples from a given station were batched on a monthly basis and subjected to radiochemical analysis for ^{239}Pu . The procedure included acid dissolution with ion exchange recovery and electroplating onto stainless-steel discs, which was followed by alpha spectroscopy using solid-state surface barrier detectors (REECO 1978a). This analysis provided a nominal minimum detection limit of 3×10^{-7} $\mu\text{Ci}/\text{m}^3$ (Lantz 1978a). Routine analysis for ^{238}Pu started in 1989 (Wruble and McDowell 1990a).

In 1977, a separate sampler was designed for the collection of airborne tritium (HT) and HTO. The sampler was portable and capable of unattended operation for up to 2 weeks in desert areas. A small electronic pump drew air into the sampler at about 0.5 L/min, and the HTO was removed from the air stream by a silica gel drying column. The dry air then passed through a catalytic converter with platinum to generate HTO from HT. Another drying column collected the vapor, in which a small volume of distilled water served as a trap for the HTO. Appropriate aliquots of condensed moisture were obtained by heating the silica gel. Counting via liquid scintillation techniques allowed for the determination of the HT and HTO activities. The typical minimum detection limit for this analysis was 3×10^{-7} $\mu\text{Ci}/\text{m}^3$ (REECO 1978a).

The total number of air sampling stations increased over the years to a peak of 52 in 1989 (Wruble and McDowell 1990a). This number remained fairly constant until a gradual reduction began in 1995 (Black and Townsend 1996). This reduction occurred primarily because of a gradual strategy shift from environmental monitoring to demonstration of compliance with National Emission Standards for Hazardous Air Pollutants as approved by the U.S. Environmental Protection Agency (i.e., 40 CFR Part 61) (Black and Townsend 1997). Figure 4-1 shows the locations of the 48 sampling stations in 1997 (Black and Townsend 1998).

Since the late 1980s, the environmental surveillance program has routinely monitored atmospheric concentrations of tritium, ^{238}Pu , ^{239}Pu , and ^{240}Pu . These radionuclides were considered the most important to dose for workers and members of the public (Wruble and McDowell 1990a). In addition, since the mid-1960s, measurements have been reported for gross alpha and gross beta concentrations (Glora and Brown 1964b). The following sections discuss the history of these measurements in the NTS annual environmental reports (see Reference section) and their importance to dose reconstruction for unmonitored employees.

4.2.1.2.1 Annual Inhalation Intakes of Tritium

Atmospheric measurements at NTS began in 1977 with samplers in Areas 5, 10, and 23 (REECO 1978a). The sampler near Building 650 (Mercury) was designated as the control station. During that year, the samples in Area 10 (near the Sedan Crater) demonstrated the highest tritium (HTO)

concentrations with a high of 3.0×10^{-4} pCi/m³ (REECO 1978a). The number of sampling locations increased over the following years to include all the areas in Table 4-1. These locations provided representative samples from the most populated areas on the site (Black and Townsend 1998).

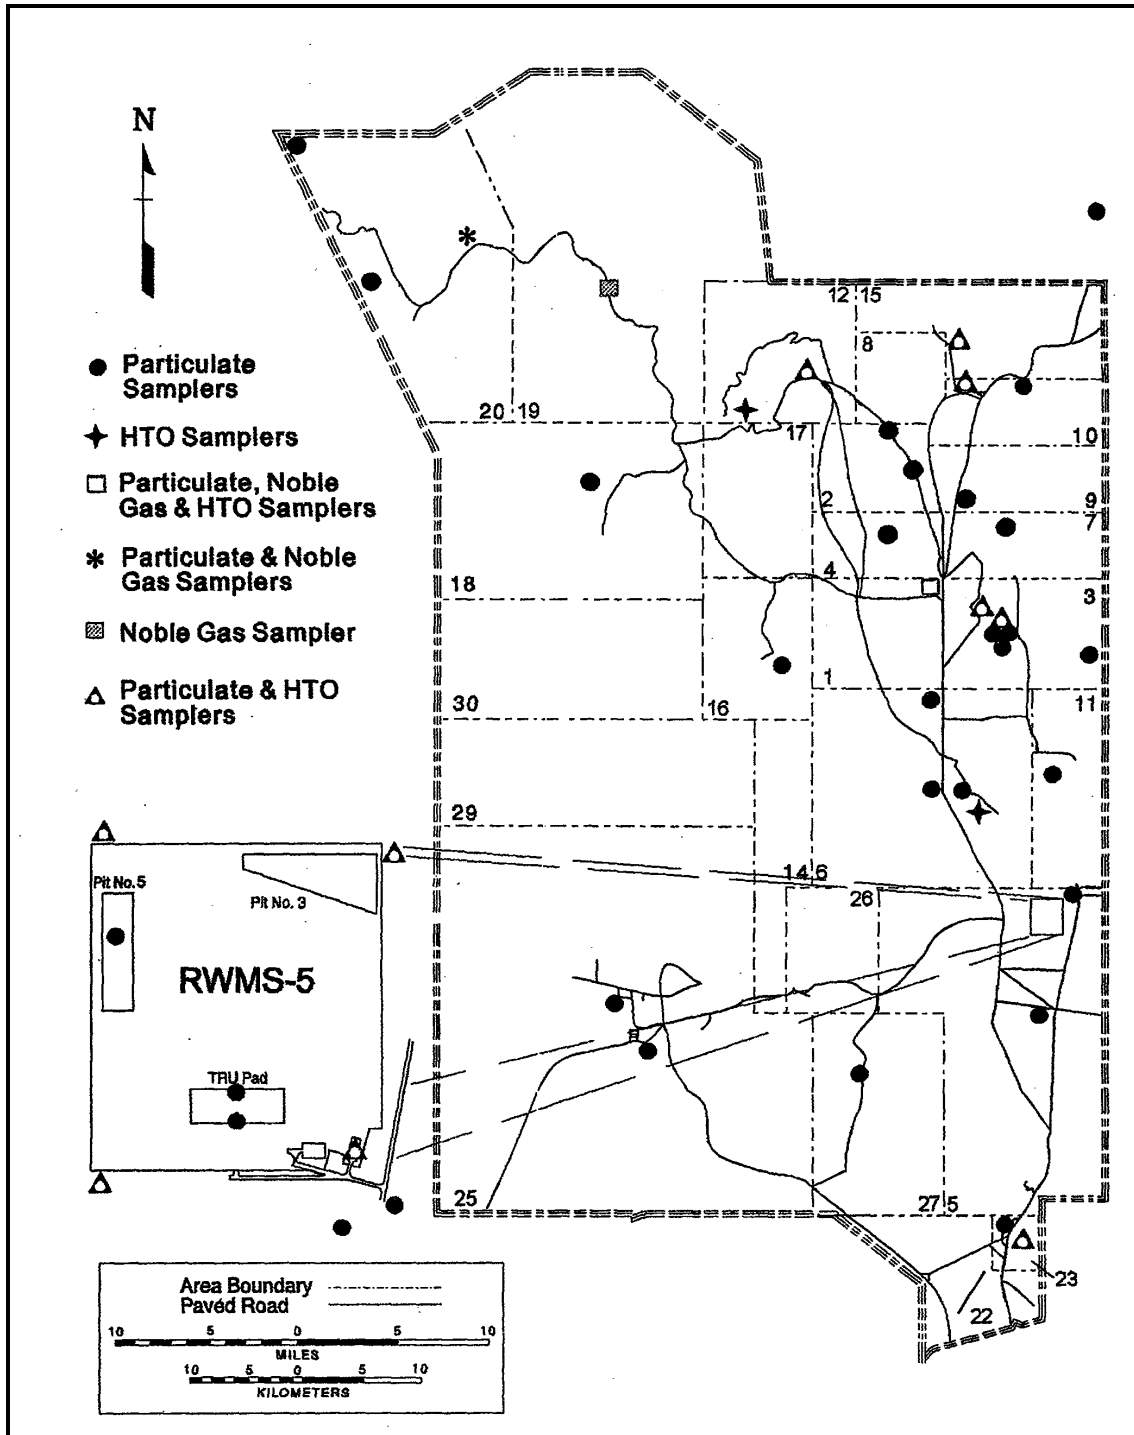

Figure 4-1. Air sampling stations in 1997.

The tritium concentrations in Table 4-1 are typically the average of the maximum concentrations for a given area in a given year, except when these values were determined to be adversely affected by nearby point-source releases (e.g., Building 790 in 1983; Scoggins 1983, p. 29). In cases where maximum values were not provided, the average concentrations were reported.

Table 4-1. HTO atmospheric concentrations (pCi/ml) by year and area with estimated maximum and average annual organ dose (mrem).^a

Year	Area at NTS												Site average (pCi/ml)	Site maximum (pCi/ml)	Site maximum annual dose (mrem)	Site average annual dose (mrem)

a. Sources: Environmental Reports list in the References section.

b. Value not provided in annual reports - assumed same as for 1978.

In addition to the annual area tritium concentrations, Table 4-1 provides NTS site average and maximum concentrations, which represent the arithmetic averages of the concentrations of all the areas and the maximum of all the areas, respectively. For purposes of dose reconstruction, these average and maximum site concentrations have been converted to annual organ dose using the dose conversion factor for inhalation of 1.80×10^{-11} Sv/Bq (ICRP 1998) and by assuming submersion in the respective concentrations for 2,000 hr/yr and an inhalation rate of 2,400 m³/yr.

In addition to the inhalation dose, a factor of 1.5 was included in the organ dose calculation to account for absorption through the skin.

The uncertainty that is associated with the values in Table 4-1 was not provided in the annual environmental report until 2001. Based on the values that were provided for that year, the standard deviation would be typically less than 10% of the measured values. Because sampling methods were changed over time and the unavailability of uncertainty estimates for previous years, the favorable to claimant assumption is made that the 50th-percentile expected intakes are those in Table 4-1 and the 95th-percentile values are twice the Table 4-1 values.

For purposes of dose reconstruction, the geometric standard deviation (GSD) of the values in Table 4-2 would be estimated by using the following expression for a lognormal distribution:

$$GSD = \left(\frac{95th\ percentile}{50th\ percentile} \right)^{\left(\frac{1}{1.645} \right)} \quad (4-1)$$

If the assumption is made that the 95th-percentile values are twice the Table 4-1 values, then the GSD can be shown using Equation 4-1 to be 1.52.

If the favorable to claimant assumption is used to estimate the 95th-percentile dose (i.e., add 100%) from the maximum annual doses in Table 4-1, the resultant annual organ doses would still be less than 2 mrem/yr.

4.2.1.2.2 Annual Intakes of Plutonium

Routine isotopic atmospheric measurements of plutonium at NTS began in 1971 with samplers in 15 locations across the site (REECO 1978a). Six additional sampling stations were added in 1978 (REECO 1979). Equipment at fixed locations continuously sampled the ambient air to monitor for radioactive materials. These locations were chosen to provide representative samples from the populated areas on the site as well as to monitor resuspension of low-fired plutonium that was spread by safety experiments before 1960 in Areas 2, 3, 4, 7, 9, and 10. Access, worker population, geographical coverage, presence of radioactivity, and availability of electric power were considerations in the site selection for air samplers (Black and Townsend 1997).

In 1988, efforts to monitor radioactive air emissions at NTS were increased as a result of the requirements of DOE Order 5400.1. Known and potential effluent sources throughout NTS were assessed for their potential to contribute to public dose (Black and Townsend 1997).

The ²³⁹Pu concentrations in Table 4-2 for 1989 through 2001 represent the average of the maximum concentrations for a given area in a given year. In cases where maximum values were not provided (i.e., 1971 through 1988), the average of the average concentrations was reported. In addition to the annual area concentrations, Table 4-2 provides NTS site average and maximum concentrations, which represent the arithmetic averages of the concentration of all the areas and the maximum of the area maximum or area averages of all the areas, respectively. Potential intakes associated with these concentrations can be calculated under the assumption that an unmonitored worker was

occupationally exposed for 2,000 hr/yr and a breathing rate of 2,400 m³/yr. Table 4-3 presents these calculated intakes.

Table 4-2. Atmospheric concentrations of ²³⁹Pu for sampled areas (pCi/m³).^a

It should be noted that some covered employees remained on the site continuously for weeks at a time. However, because most of the nonworking hours were spent indoors where ambient air particulate loadings would be much less than the outdoor loadings and because of the conservative assumptions that were used to estimate the values in Table 4-3, adjustment of the tabular data is not required to ensure intakes are not underestimated for these individuals. In addition, employees who lived on the site during their work week would have been housed in Area 12 or Area 23 (Mercury). For most years, the values in Table 4-2 for these locations are less than the site average values. For purposes of dose reconstruction, the inhalation intake values in Table 4-3 can be assumed to be bounding; therefore, the organ dose that results from these intakes should be applied with a constant distribution.

It is assumed that plutonium could be any of absorption Type S, Super S, or M dependent on which type delivers the maximum organ dose. Because these doses are based on air monitoring results, evaluation for Super S (ORAUT 2007a) is required for lung and thoracic cancers if there were no bioassay results for the employee.

4.2.1.2.3 Annual Intakes of Other Radionuclides

Extensive studies were performed in the 1980s to quantify residual contamination at NTS (McArthur 1983, 1985, 1987, 1988, 1989, 1991). Table 4-4 lists the results of these studies (McArthur 1991). Table 4-5 lists the total areal depositions based on the inventory values in Table 4-4 divided by the respective areal size. It should be noted that the results in Table 4-5 are representative of areas of the NTS that have been shown to contain measurable levels of contamination. These areas actually represent only about one-third of the total area within the boundaries of NTS.

Table 4-4. Inventory of contaminated soil (Ci).

Source: McArthur (1991).

In addition, because the data in Table 4-4 is representative of the soil contamination in 1991, the values in Table 4-5 were decay-corrected to the beginning of 1963 – the first year after the cessation of atmospheric testing.

4.2.1.2.4 Scaling Factors for Inhalation Intakes

Because the air sampling program did not provide isotopic analyses for all of the radionuclides identified in the NTS soils, scaling factors are developed to estimate potential intakes for these radionuclides based on the relative abundances of these radionuclides compared to ²³⁹Pu when the soil contamination data (McArthur 1991) has been decay corrected to 1963. These area-specific ratios are provided in Table 4-6.

Table 4-6. Abundance of radionuclides in NTS soils relative to ²³⁹Pu decay-corrected to 1963.

Area	Am-241	Pu-238	Pu-239,240	Co-60	Cs 137	Sr-90	Eu-152	Eu-154	Eu-155

Maximum scaling factor	0.586	0.912	1.000	7.64	2.08	4.07	8.93	0.378	5.85
Scaled maximum intake (Bq/yr)	0.223	0.347	0.381	2.91	0.792	1.55	3.40	0.144	2.23

The scaling factors in Table 4-6 are used in conjunction with the ^{239}Pu intakes in Table 4-3 to determine the potential environmental intakes of all the radionuclides important to dose (in Table 4-6) that have been identified as persistent in NTS soils. For purposes of dose reconstruction, maximum intakes of these radionuclides are calculated by selecting the maximum annual intake of plutonium (i.e., 0.381 Bq/yr derived for Area 9 in 1972) and multiplying this value by the maximum scaling factor for each of the radionuclides in Table 4-6.

4.2.1.2.5 Correction for Resuspension for Early Times after Atmospheric Tests

Anspaugh (2002) stated that, based on empirical observations, concentration of resuspended radionuclides in air have been noted to display a strong time dependence at early times after deposition and that this pathway could be important for reoccupation of contaminated property. He goes on to state that there has not been universal agreement that resuspension is an important pathway but that it is now generally accepted that there are a few instances where the pathway could be the dominant one. Many observations have shown that the rate of resuspension decreases rapidly with time and, for accident situations, resuspension is only of importance (in comparison with the inhalation exposure from the initial cloud passage) over short periods. For this reason, Anspaugh (2002) states that the resuspension factor model has been widely used to predict the concentration of resuspended radionuclides at early times after initial deposition while the mass loading model (which uses measurements of dust loading in air and soil contamination data to predict air concentration of radionuclides) has generally been preferred for times long after deposition. However, Anspaugh also states that it is always preferable to rely on actual measurements that are performed over long periods (such as those in Section 4.2.1.2.2).

Anspaugh (2002) presents several resuspension models that have been proposed but concludes that they can be over- or under-predictive at various times after deposition when compared to empirical observations. However, with expanded data sets from the work of Hicks (1981e) and others in the 1980s, Anspaugh has proposed a resuspension model that more accurately describes the observed results over the entire time span of the expanded data set for the NTS:

$$S_f = \left[10^{-5} e^{-0.07t} + 6 \times 10^{-9} e^{-0.003t} + 10^{-9} \right] \times 10^{\pm 1} \text{ m}^{-1} \quad (4-2)$$

A graphical depiction of Equation 4-2 is provided in Figure 4-2 from time t equal zero to 1,000 d after detonation. As shown in Figure 4-2, the resuspension factor S_f ranges from about 10^{-5} at times early after deposition, falls rapidly during the first 100 or so days to a value of about 10^{-8} , and then approaches a value of 10^{-9} after a few years. The factor of 10 at the end of the equation is a statement of uncertainty in the model.

If it is true that the mass loading approach is more predictive at time long after initial deposition and that the resuspension proposed by Anspaugh is predictive of the observed results over the expanded dataset (including those that were developed in the 1980s), then the factor of 10^{-9} could be taken to be the resuspension factor that would be predictive of the mass loading process that is thought to be more important during the times when the air monitoring data are available (i.e., 1971 through 2001, see Section 4.2.1.2.2).

When Anspaugh's proposed resuspension model (i.e., Equation 4-2) is integrated over 180 to 545 days and compared to the result of the integral of the constant 10^{-9} over the same period, a factor is developed that can be used to correct the intakes derived from air sampling data (i.e., times long after initial deposition) for the early resuspension phenomenon that has been observed at the NTS.

Figure 4-2. Resuspension factor as a function of time after initial deposition (from Attachment A).

The period of integration was selected to begin at day 180 because the last atmospheric tests at the NTS were in July of 1962 and therefore about 180 d had passed before the beginning of 1963 (the starting date for reconstruction of internal dose at the NTS in the absence of bioassay results for the employee). For the Anspaugh (2002) model, the early resuspension correction factor has been determined to be 3.12. In a similar manner, correction factors for 1964 and 1965 were determined to be 1.72 and 1.24, respectively. Thus, for dose reconstruction purposes, the scaled maximum inhalation intakes in Table 4-6 should be multiplied by these factors to account for early resuspension from 1963 through 1965. If necessary, these intakes can be prorated for time less than a year for a best estimate if the worker was on the site for only a fraction of the year.

4.2.1.2.6 Correction for Inhalation Dose from Short-Lived Fission and Activation Products

Correction factors were developed to account for inhalation intakes of short-lived fission and activation products based on organ-specific dose from the ^{90}Sr intakes in Table 4-7 (from Attachment A). These corrections are shown in Table 4-8.

Table 4-7. Scaled inhalation intakes corrected for early resuspension (Bq/yr).

Year of intake	Am-241	Pu-238	Pu-239, 240	Co-60	Cs 137	Sr-90	Eu-152	Eu-154	Eu-155
1963	0.70	1.08	1.19	9.08	2.47	4.84	10.61	0.45	6.96
1964	0.38	0.59	0.65	4.98	1.35	2.65	5.81	0.25	3.81
1965	0.28	0.43	0.47	3.61	0.98	1.92	4.22	0.18	2.77
All subsequent years	0.223	0.347	0.381	2.91	0.792	1.55	3.40	0.144	2.23

The Integrated Modules for Bioassay Analysis (IMBA) computer program was used to determine the organ doses resulting from the scaled intakes of ^{90}Sr in Table 4-7 for a period of 10 years (i.e., 6.20 Bq for 1963 and 1.68 Bq/yr from 1964 through 1972). These doses were then multiplied by the correction factors in Table 4-8 to determine the additional dose that should be added to account for potential dose from inhalation of short-lived fission and activation products. The organ-specific fission and activation doses greater than 0.001 rem are provided in Table 4-9. Other organs are not shown in Table 4-9 because all were less than 0.001 rem. These doses should be added to the input for the

Interactive RadioEpidemiological Program (IREP) as a constant as 100% 30- to 250-keV photons. These doses are input as constants because they are based on bounding intakes (i.e. maximum) and they are entered as 30- to 250-keV photons as an assumption favorable to claimants.

4.2.2 Annual Intakes from Ingestion

To account for potential intakes from inadvertent ingestion of contaminated soil, the area-specific radionuclide soil deposition data in Table 4-5 were converted to volumetric data (i.e., Bq/g) by assuming a radionuclide relaxation depth of 2.3 cm (DOE 2003) and a soil density of 1.5 g/cm³ (DOE 2003). The area-specific radionuclide soil concentrations are presented in Table 4-10.

If the assumption is made that the workers ingested 100 mg of soil each day (EPA [1989] recommends a value of 50 mg/d) and the assumption is made that full-time employment was 250 d/yr, annual ingestion can be calculated in a manner favorable to claimants. The area-specific annual ingestion rates are in provided in Table 4-11.

It should be noted that for most radionuclides, Area 30 provided the highest areal deposition and resultant intakes. Area 30 is relatively small (150 km²), inaccessible, and is located on the Western edge of the NTS. It has rugged terrain and includes the northern reaches of Fortymile Canyon. In 1968, it was the site of Project BUGGY, the first nuclear row-charge experiment in the PLOWSHARE Program. As a result of the test, a trench 255 m long, 77 m wide, and 206 m deep was created. The test resulted in large quantities of vitrified glass. Because of the bias that is introduced when Area 30

a. Maximum value with Area 30 excluded.

is included, the maximum annual intakes in Table 4-11 have been provided without the Area 30 areal concentrations.

Similar to what was done for inhalation intakes, a method was developed to adjust ingestion doses for potential dose resulting from short-lived fission and activation products that are no longer persistent in the NTS soils in measurable amounts. The organ-specific fission and activation product correction

factors were developed based on the relative contribution of ⁹⁰Sr to the total ingestion dose. These correction factors are presented in Table 4-12.

Table 4-12. Organ-specific ingestion fission and activation correction factors (from Attachment A).

To simplify the application of organ-specific ingestion dose from short-lived fission and activation products, the IMBA computer program was used to determine the organ-specific annual doses for the ⁹⁰Sr intake of 55.42 Bq/yr for 1963 through 1972. These doses are shown in Table 4-13. The doses in Table 4-13 are then multiplied by the Table 4-12 organ-specific correction factors to provide the annual doses resulting from ingestion of short-lived fission and activation products. The annual organ-specific doses that were determined to be greater than 0.001 rem are provided in Table 4-14.

Table 4-13. Organ-specific annual ingestion doses (rem) for the ⁹⁰Sr intake of 55.42 Bq/yr.

4.3 OCCUPATIONAL EXTERNAL DOSE

Workers incur external doses from the ambient radiation levels and from noble gases. Ambient radiation measurements were reported in NTS annual environmental reports (see References section) starting in 1967; however, no ambient radiation data were provided in the reports for 1968 to 1976.

4.3.1 Ambient Radiation

Before 1967, ambient radiation levels that were unaffected by weapons testing were not reported in the annual environmental reports. Although there were many radiation measurements completed between 1951 and 1967, most of these were to characterize the effects of weapons tests and were therefore not appropriate for use in estimating external environmental dose for unmonitored employees.

In 1967, ambient radiation levels were measured using Victoreen Model 239 indirect reading ionization chambers with effective ranges of 0 to 10 mR/hr. Five of these chambers were in small, semiprotective enclosures in NTS living areas (REECO 1968). As a backup for the ionization chambers, standard NTS film dosimeters were included at each sample location. However, all results from these film dosimeters for 1967 were either zero or lost due to light or heat damage. Results from environmental NTS film dosimeters were subsequently discarded because of the likelihood of heat damage.

The ionization chambers were collected on a weekly basis and read on a Victoreen Minometer II reader. Corrections were made for background and for nonradiation induced drift. Two sets of chambers were used, one set at the sample locations for measurements and another set stored fully charged in the laboratory. Each week these sets were exchanged, the fresh set being recharged and a record kept of the amount of "drift" while stored in the laboratory. A specially designed shock-proof box for transportation minimized accidental discharge from mechanical shock.

Readings from the five chambers in each location were averaged to obtain a mean value for each location each week. Readings significantly higher than others at a particular location were not used in compiling the data because the abnormal readings were most likely the result of shock or other malfunction and were not representative measurements. Because of the method of background subtraction that is discussed above, the data in the 1967 annual report were assumed to be due to manmade radiation in excess of natural background.

No results were reported between 1968 and 1976 in the NTS annual environmental reports, however, ambient radiation reporting was reestablished in 1977 using thermoluminescent dosimeters (TLDs) (REECO 1978a). The dosimeters used were CaF₂:Dy (TLD-200) 0.25- by 0.25- by 0.035-in. chips from Harshaw Chemical Company. A badge that consisted of at least two chips shielded by 0.047 in. of cadmium (1030 mg/cm²) inside a 0.050-in. black plastic (140 mg/cm²) holder was placed about 1 m above the ground at each of 10 locations that coincided with air sampling stations. These sites were selected because of their proximity to workers. During that year, the natural background ambient radiation level was established at 0.26 mrem/d or about 95 mrem/yr.

In 1987, the Harshaw dosimeters were replaced with Panasonic Model UD-814 TLDs (Gonzalez 1988). These specifically designed environmental dosimeters contain three identical $\text{CaSO}_4:\text{Tm}$ elements and one $\text{Li}_2\text{B}_4\text{O}_7:\text{Cu}$ element. The lithium element is shielded with 14 mg/cm^2 of material to monitor beta particles in the environment. The three calcium elements are encapsulated in $1,000 \text{ mg/cm}^2$ of plastic and lead to monitor ambient gamma levels. The UD-814 TLDs have remained in use to the present time.

In subsequent years, the number of sampling locations increased to over 150 and eventually covered all populated areas at NTS. Table 4-15 lists average ambient background radiation levels. Table 4-16 lists the annual measured ambient radiation including background and site average and maximum values. For purposes of dose reconstruction, because the values in Table 4-16 represent continuous exposure for an entire year, these values should be adjusted for occupational exposure (i.e., 2,000 hr/yr) and added to the dose of record for unmonitored employees. If the area in which the employee worked is known, the average value for that area should be used. If the area in which the employee worked is not known, the site maximum value should be used to be favorable to claimants.

Table 4-15. Ambient background radiations levels by year.^a

Year	mrem/yr	Year	mrem/yr	Year	mrem/yr

- b. Not reported.

It should also be noted that some covered employees remained onsite continuously for weeks at a time. However, because most of the non-working hours were spent indoors where elevated ambient radiation would be reduced by shielding from the building and because of the conservative assumptions used to estimate the values in Table 4-16, adjustment of the tabular data is not required to ensure ambient exposures are not underestimated for these individuals.

It is likely that the elevated ambient radiation peaked in the early 1960s near the end of aboveground testing. Therefore, it would be reasonable and probably favorable to claimants to assign maximum annual environmental doses for 1963 through 1966 equal to the maximum value reported for 1967 (i.e., 318 mrem/yr). It should be noted that for 1967, the maximum value is about 50-percent higher than the average value for all areas where measurements were reported. Following this logic, maximum doses have been added to Table 4-16 (shown in italics) for 1969 through 1977 for which data were not readily available. These values were based on the maximum value for 1978 and should be used to adjust environmental dose for unmonitored employees for those years.

Table 4-16. Ambient radiation by area (mrem/yr).^{a,b}

- Sources: Environmental Reports list in the References section.
- Blank cells indicate data not available.
- Ambient radiation not provided for these years - assumed equal to value for 1978.

Although not explicitly stated in the NTS annual environmental reports, the overall uncertainty of measurements from modern TLDs (e.g., Panasonic UD-814) has been determined to be less than 20% (ORAUT 2007b). However, for earlier measurement methods, the overall uncertainty could have been greater. Therefore, for purposes of dose reconstructions that are favorable to claimants, the assumption is made that the 95th-percentile values of the expected values (50th percentile) in Tables 4-15 and 4-16 are enveloped by a factor of ± 2 of the overall error of 50% (i.e., $\pm 100\%$). Equation 4-1 (Section 4.2.1.2.1) would then estimate the GSD for the expected values at 1.52.

4.3.2 Releases of Noble Gases

Ground seepage can increase when changes in ambient pressure pump small amounts of noble gases (primarily ^{85}Kr and ^{133}Xe) up through the overburden and into the atmosphere from the cavity that is created by a nuclear test. This process, sometimes referred to as *atmospheric pumping*, creates a diffuse source of radiological effluents.

In 1982, REECo assumed responsibility for six noble gas sampling stations EPA previously ran and replaced them with new samplers. These sampling units are housed in a metal tool box with three metal air bottles attached with quick disconnect hoses. A vacuum is maintained on the first bottle, which causes a steady flow of air to be collected in the other two bottles. The flow rate is approximately $0.5 \text{ cm}^3/\text{min}$. The two collection bottles are exchanged weekly and yield a sample volume of about $3 \times 10^5 \text{ cm}^3$ (Scoggins 1983).

The noble gases are separated and collected from the atmospheric sample by a series of cryogenic-gas chromatographic techniques. Water and carbon dioxide are removed at room temperature and the krypton and xenon are collected on charcoal at liquid nitrogen temperatures. These gases are transferred to a molecular sieve where they are separated from any remaining gases and each other. The krypton and xenon are transferred to separate scintillation vials and counted on a liquid scintillation counter. The lower limits of detection for krypton and xenon are 4×10^{-6} and $10 \times 10^{-6} \text{ pCi/m}^3$, respectively (Scoggins 1983).

Krypton-85

The original six samplers were in Areas 1, 5, 12, 15, 23, and 25. These six samplers showed no statistical difference in atmospheric concentrations of ^{85}Kr during 1982 and 1983. The average

concentration of all stations for these years was 24.6 pCi/m³ (0.91 Bq/m³), which was established as NTS background. This background measurement shows good agreement with the global background of 27 pCi/m³ (1.0 Bq/m³) (WMO 2002).

In 1983, REECo measured a statistically significant elevation in ⁸⁵Kr concentrations in Area 20 of 4.0 pCi/m³ (0.15 Bq/m³) above background, which was subsequently related to seeps from nuclear cavities on Pahute Mesa (Scoggins 1984). These elevated concentrations continued until after the cessation of nuclear testing in 1992. Table 4-17 lists the average background and the Area 20 elevated concentrations from 1983 through 1992.

- a. Sources: Environmental Reports list in the References section.
- b. Source receptor location assumed to be 500 m from U-20a emplacement hole.
- c. Includes gonads, breast, lung, red marrow, bone surfaces, thyroid, remainder, and effective whole body.
- d. Assumes 2,000 hr/yr exposure and dose conversion factor of 2.2×10^{-16} Sv/Bq/s/m³ (Eckerman and Ryman 1993).
- e. Assumes 2,000 hr/yr exposure and dose conversion factor of 1.32×10^{-14} Sv/Bq/s/m³ (Eckerman and Ryman 1993).

The source of the elevated ⁸⁵Kr concentrations was attributed to the emplacement hole nearest to the Area 20 sampler (U-20a), which is about 3,660 m (12,000 ft) to the south. To determine whether these elevated concentrations could be of any consequence for unmonitored workers, upper-bound concentrations of ⁸⁵Kr within 500 m of U-20a were estimated using Area 20 meteorological data station files and the CAP88-PC (EPA 1998) computer program. The program was used to develop atmospheric dispersion factors (*X/Q*) for various distances from the source of emissions. The ratio of the *X/Q* value at 500 m to that at 3,660 m was determined to be about 27, which means that the ⁸⁵Kr concentration 500 m from the source could, on average, be 27 times greater than that measured at the sampler location. The potential dose resulting from submersion in the plume of this noble gas is considered to be entirely external because the gas is not readily assimilated by the body. Therefore, these source concentrations were converted to potential organ doses using submersion dose conversion factors from Federal Guidance Report No. 12 (Eckerman and Ryman 1993).

As Table 4-17 shows, the upper-bound annual organ doses for all years are less than 1 mrem. For purposes of reconstructing environmental doses for unmonitored employees, these doses are inconsequential for determination of probability of causation and therefore should be ignored. In addition, if a monitored employee was exposed to the calculated upper-bound ⁸⁵Kr concentrations or significantly higher concentrations during work activities, these exposures would have been monitored by personal dosimeters and would, therefore, already be present in the individual dosimetry record.

Uncertainty estimates provided for a number of the ⁸⁵Kr measurements indicate, generally, a standard deviation of less than 20% of the measured value. Even at the 2-sigma level of ±40 percent, the annual organ doses in Table 4-17 are less than 1 mrem and therefore inconsequential for employee dose reconstruction.

Xenon-133

Although the vast majority of the ^{133}Xe measurements were below the lower limit of detection (i.e., 10×10^{-6} pCi/m³), elevated atmospheric concentrations of ^{133}Xe were occasionally measured in Area 20. Like ^{85}Kr , these elevated concentrations were attributed to seepage from the underground test cavities at the Pahute and Rainier Mesa tests (Fauver 1985). However, ^{133}Xe has a short half-life (5.25 days versus 10.7 years for ^{85}Kr). Therefore, these elevated concentrations were short lived. In addition, these elevated ^{133}Xe concentrations were always less than the derived air concentrations (typically less than 3%) and would result in annual organ doses of less than 1 mrem. Therefore, potential doses to unmonitored employees from elevated concentrations of ^{133}Xe are inconsequential for dose reconstruction.

4.4 INTERNAL INHALATION AND INGESTION DOSE TO UNDERGROUND WORKERS

In the early 1980s, the Environmental Sciences Department of REECo recognized that the buildup of radon and radon daughter concentrations (RDCs) could pose a potential health problem in tunnels on Rainier Mesa and at other locations at the Nevada Test Site. In 1984, to determine the concentrations of the RDCs and the effect of environmental conditions on the buildup of these concentrations, REECo conducted radon measurement surveys in G-, T-, and N-Tunnels (Favor 1987). This section discusses the results of these surveys and those conducted in 1991 and 1992 (Lyons 1992a,b).

4.4.1 Underground Activities

Area 12, which is in the Nuclear or High Explosive Test Zone, occupies 104 km² (40 mi²) at the northern boundary of NTS, known as Rainier Mesa. No atmospheric nuclear tests have occurred at this location; however, Area 12 was the site of the U.S. Atomic Energy Commission's first fully contained underground nuclear detonation, named the Rainier test, on September 19, 1957, in a horizontal tunnel about 487 m (1,600 ft) into the mesa and 274 m (900 ft) beneath the top of the mesa (ORAUT 2007c). In the past several decades, a number of tunnels have been mined into Rainier Mesa, in which most of the U.S. Department of Defense (DOD) horizontal line-of-sight exposure experiments have occurred. The N-, P-, and T-tunnel complexes, in particular, were developed extensively during the 1970s and 1980s. The tunnel experiments usually involved complex construction of large-diameter (up to 9 m [27 ft]), line-of-sight pipes and special closure mechanisms, blast and gas seal doors, stemming plugs, and the like. The G-tunnel complex was originally established for nuclear testing purposes but, since 1971, has been used only as an underground research facility (ORAUT 2007c).

In addition to its use for nuclear testing purposes, N-tunnel was the location of a Nonproliferation Experiment involving 1.3 million kg (2.9 million lb) of conventional explosives on September 22, 1993. DOD operates a high-explosives research and development tunnel in Area 12. This reusable test bed supports programs involving the detonation of conventional or prototype high explosives and munitions (ORAUT 2007c).

The U1a Complex in Area 1 is an underground laboratory of horizontal tunnels about 0.5 mi in length at the base of a vertical shaft about 960 ft beneath the surface. The vertical shaft is equipped with a mechanical hoist for personnel and equipment access. Another vertical shaft about 1,000 ft away provides cross ventilation, instrumentation, utility access, and emergency egress. The shaft was excavated in the 1960s, and a nuclear test was conducted in a horizontal tunnel mined from its base in 1990 (ORAUT 2007c).

4.4.2 Radon Measurements

Radon-222, with a radioactive half-life of 3.8 days, occurs in the ^{238}U decay chain; ^{220}Rn , with a radioactive half-life of 54.5 s, occurs in the ^{232}Th chain. The decay daughters associated with ^{222}Rn

include ^{218}Po , ^{214}Pb , ^{214}Bi , and ^{214}Po , and those associated with ^{220}Rn include ^{216}Po , ^{212}Pb , ^{212}Bi , and ^{208}Tl . Because radon is a noble gas and thus chemically inert, it migrates easily from the tunnel rock and soil, which contains naturally occurring trace quantities of uranium and thorium.

Radon progeny measurements in N- and T-Tunnels were made in drifts mined in a rock formation known as Tunnel Bed Non-Welded Ash Fall Tuff. This rock is unconsolidated and only slightly fractured. The drift that was sampled in the inclined G-Tunnel was mined in Grouse Canyon Welded Ash Fall Tuff, which is extremely fractured. Some factors that affect concentrations of radon and radon progeny in air are ventilation rates, barometric pressure, relative humidity, temperature inversions, the degree of fracturing in the rock, and the amount of smoke and dust in the air. Factors such as barometric pressure and fractures affect the rate at which radon emanates from the rock, while others such as dust and ventilation rates affect the accumulation rate of progeny in the air. Concentrations fluctuate with changing seasons, weather conditions, and activities in the area being monitored (Fauver 1985).

The concentration of radon progeny (the major dose contributors) in air is measured in working levels (WL). This is the common unit for expressing radon progeny exposure rates. The WL was developed for use in uranium mines but is now also used for environmental exposures. Numerically, the WL is any combination of short-lived decay products in 1 L of air that results in the emission of 1.3×10^5 MeV of potential alpha energy. When radon is in complete equilibrium with its short-lived decay products, 1 WL equals 100 pCi/L (i.e., 100 pCi/L each of ^{222}Rn and short-lived decay products ^{218}Po , ^{214}Pb , ^{214}Bi , ^{214}Po) (NCRP 1988, p. 17). For ^{220}Rn and its decay products (^{216}Po , ^{212}Pb , ^{212}Bi , and ^{208}Tl), 1 WL is equal to 7.47 pCi/L. The advantage of the WL unit is that it allows comparison of different equilibrium levels and different concentrations of radon decay products. The degree of equilibrium is a critical factor for estimating inhalation exposure and is of equal importance to the radon concentration itself (NCRP 1998, p. 19). The WL unit considers this factor. However, because the dose conversion factors for ^{220}Rn progeny ($^{212}\text{Pb} + ^{212}\text{Po}$) are one-third the values for the ^{222}Rn progeny (ICRP 1981), the dose equivalent WL for ^{220}Rn is only one-third that of a ^{222}Rn WL.

The exposure of tunnel workers can be expressed in units of working-level months (WLM), which is an exposure rate of 1 working level (WL) for a working month of 170 hours (NCRP 1988, p. 17). For example, an exposure of 1 WLM would result from exposure to a concentration of 1 WL for 1 month or 0.5 WL for 2 months.

4.4.3 Underground Radon Concentrations

Measurements were taken in tunnels N, T, and G. The preliminary measurements indicated N- and T-Tunnel RDCs of about 0.01 WL under normal ventilation conditions. However, the data demonstrated that RDCs could rise to relatively high levels (i.e., 0.24 WL) when ventilation rates were significantly lower (Favor 1987, Figure 2, p. 7). The radon daughter concentrations in G-Tunnel were an order of magnitude higher than those in N- and T-Tunnels. The average RDC in the rock mechanics drift (the worst-case location in G-Tunnel) was 0.13 WL (ranging from 0.07 to 0.23 WL). Elevated RDCs in the rock mechanics drift of G-Tunnel seemed to be from a lower ventilation rate in conjunction with the more highly fractured nature of the welded tuff in which the incline drift was mined. By increasing the ventilation rate, a 60% reduction in RDCs from an average of 0.13 WL to an average of 0.05 WL was achieved (Table 4-18).

Table 4-18. Results of experiment to determine the effects of ventilation conditions on RDCs in the G-Tunnel inclined drift.^a

Location	Ventilation conditions	Radon daughter integrated sample average (WL)
Rock mechanics drift at 0+52	Alternating	0.19
	Continuous	0.05
Average	Alternating	0.13
	Continuous	0.03

a. Source: Fauvor (1985, Table 3).

Lyons (1992a,b) reported additional radon measurements from 1991 and 1992. Although the G-Tunnel complex remained inactive during 1992, radon samples were taken to document potential radon WL in a worst-case scenario of complete ventilation failure throughout the complex. The maximum WL for radon daughters was 1.4. No samples were taken during 1992 in T-Tunnel, which was inactive that year.

Tables 4-19 and 4-20 list the results of extensive radon sampling in N- and P-Tunnel complexes in 1992 (from Lyons 1992a, Table 3, p. 8; and Lyons 1992b, Table 1, p. 8, respectively). The average concentrations in N- and P-Tunnels were 0.021 and 0.009 WL, respectively, and the maximum concentrations in N- and P-Tunnel were 0.038 and 0.017 WL, respectively.

4.4.4 Underground Workers' Exposure to Radon

Although measurements were periodically performed in the tunnel complexes to ensure adequate worker protection, neither the U.S. Department of Energy nor its predecessor agencies attempted to quantify or record occupational exposures to radon and its daughters. Therefore, dose reconstructors should adjust the dose for lung, ET1, and ET2 cancers of any employee who was a miner or tunnel worker to account for radon exposure while working in the tunnel complexes. To quantify the exposure, Table 4-21 lists favorable to claimant airborne ²²²Rn RDCs based on measurement results. It should be noted that the values provided in Table 4-21 pertain only to ²²²Rn and its daughter products. The ²²⁰Rn WL concentrations and resultant exposures for N- and P-Tunnels must be converted to annual alpha organ dose prior to entry into IREP.

Table 4-21. Annual ²²²Rn exposures and uncertainties for internal dose reconstruction for miners and tunnel workers (Fauver 1985).

Tunnel complex	RDC concentration (WL)	Annual exposure (WLM) ^a	Uncertainty GSD ^b
G (before 1984)	0.16	1.92	1.52
G (1984 and later)	0.05	0.60	1.52
N	0.013	0.16	1.52
P	0.006	0.07	1.52
T	0.01	0.12	1.52
Unidentified ^b (before 1984)	0.16	1.92	1.52
Unidentified ^b (1984 and later)	0.05	0.60	1.52

- a. Based on 170 hours of exposure per month for 12 months.
- b. Use these values when underground work location is not known.

For G-Tunnel workers, annual exposures (assuming a full year of underground activity) are assumed to be 1.92 WLM before 1984 and 0.60 WLM during and after 1984. This is because REECo did not recognize until 1984 that significant reductions in RDCs could be effected by leaving all ventilation fans running overnight. Until 1984, the practice was to shut down alternating fans each night, which resulted in higher average RDCs.

Because no radon measurement data were readily available for the underground portions of the U1a Complex, the favorable to claimant assumption was made that the RDCs in U1a would be similar to those in G-Tunnel (which is mined in highly fractured tuff) [1]. In addition, a reasonable assumption was made that the U1a Complex is well ventilated, similar to G-Tunnel. Dose reconstructors should use these average, annual exposure values for miners and tunnel workers without identified tunnel locations.

For purposes of dose reconstruction, the GSD of the values in Table 4-21 can be estimated using Equation 4-1 (Section 4.2.1.2.1). Under the assumption that the 50th-percentile expected annual

exposures are those in Table 4-21 and that the 95th-percentile values are twice the values in Table 4-21, then the GSD for the values in Table 4-21 are 1.52 for all values.

Gravel Gerties

As discussed in Chapter 2, Section 2.2.5 (ORAUT 2007c), underground bunkers were constructed in Area 5 for the purpose of testing containment capabilities involving accidental explosion of HE material in the underground bunker. Containment tests were conducted in the Gravel Gerties in 1957 and again in 1982. These tests resulted in successful designs that were used at the Pantex Plant in Texas and for use in the Device Assembly Facility in Area 6. Five Gravel Gerties were constructed in Area 6 from 1988 to 1992. However, with the cessation of testing in 1992, these Gravel Gerties have not been activated for device assembly.

Because the Area 5 Gravel Gerties were constructed for testing purposes and the Area 6 Gravel Gerties were never activated, it is not likely that workers spent significant time inside the structures. However, if it can be determined from the dosimetry records or telephone interviews that a claimant worked in the Gravel Gerties for any significant time, it should be assumed that they would have been exposed to elevated levels of radon and, therefore, this radon exposure should be evaluated and included in the dose reconstruction.

Although radon measurements are not available inside the NTS Gravel Gerties, because of the similarities of construction, application of the radon concentrations measured inside the Pantex Gravel Gerties is assumed to be appropriate. Therefore, for a 12-month period that it can be determined that a claimant worked in the NTS Gravel Gerties, a radon exposure of 0.072 WLM should be assigned (ORAUT 2007a, Section 5.3.3). This exposure may be prorated as appropriate for employment periods of less than a full year. These exposures should be applied as lognormal with a GSD of 3 (ORAUT 2007a, Section 5.3.3).

Uncertainty Associated with Radon Measurements

Two methods used to measure the concentration of radon and its progeny were the grab sample technique and the integration technique. Preliminary measurements were made by grab sampling for a general estimate of the concentrations. Lucas cells collected and counted grab samples of radon gas. The cells were evacuated in the laboratory and opened at the sampling location for a single intake of air. The filled cells were counted at the EPA Las Vegas Laboratory within 24 hours to minimize decay. The number of measurements was small due to limited availability of Lucas cells. Grab samples of radon daughters were collected and counted according to a technique described by Rolle (ANSI 1973), which utilized a single count of an air sample collected on a filter. Samples were collected on a 2-cm Whatman fiberglass filter at a rate of approximately 5 L min^{-1} and counted on an EDA Instruments Incorporated Radon Detector (Model #RD200). The Rolle method allowed for a choice of several different analysis regimes. The regime chosen for tunnel measurements was a 5-min sampling time, a 6-min decay time, and a 5-min counting time. Using appropriate correction factors, the RDC in WL can be evaluated 11 min after sample collection. The values obtained using the Rolle method were periodically checked using the Kusnetz (Favor 1987, p.3) method, which also utilized a single count of an air filter but allowed for a 40- to 90-min decay time. These measurement techniques have been found to have good accuracy and a relative standard deviation of less than 15% (Favor 1987, p. 3).

Grab sampling is quick and convenient. However, as mentioned above, radon concentrations can fluctuate widely with time and location. To account for this variability, integrating monitoring instruments were used. A passive environmental radon monitor (PERM) was used to measure radon in pCi L^{-1} . A radon progeny integrating sampling unit (RPISU) measured the RDC in WL.

The PERM is an integrating radon monitor that employs electrostatic collection of radon daughter ions and uses a TLD as the radiation dose integration element. The lower limit of detection at the 95%

confidence level is approximately 0.3 pCi L^{-1} for a 1-week sample with a relative standard deviation of 20% (Favor 1987, p. 4). The RPISU is a low-volume air sampler that draws air through a $0.65\text{-}\mu\text{m}$ -pore-size Millipore membrane filter. A Teflon disc TLD containing dysprosium-activated calcium fluoride (Harshaw TLD200) is positioned close to the collection surface of the filter and serves as the dose integrating element. The lower limit of detection at the 95% confidence level is approximately 0.0001 WL for a 1-week sampling period with a relative standard deviation of 10% (Favor 1987, p. 4). The RPISU technique is recommended for the measurement of RDCs by the Technical Measurements Center of the U.S. Department of Energy, Division of Remedial Action Projects (Favor 1987, p. 4).

4.4.5 Underground Workers' Exposure to Other Radionuclides

In addition to exposure to elevated levels of radon, underground workers may have been potentially exposed to other sources of airborne contamination. Because the breathing air in the underground environment was drawn from the outside environment, the underground workers would have been exposed to the same inhalation intakes as the aboveground workers (see Sections 4.2.1.2.2 through 4.2.1.2.6 above).

4.5 INSTRUCTION TO DOSE RECONSTRUCTORS FOR ASSIGNMENT OF ENVIRONMENTAL INTAKES

4.5.1 Assigning External Ambient Dose

Starting in April of 1957, all personnel entering the NTS were monitored for external radiation exposure (ORAUT 2007b). Because unexposed control badges were processed together with the personnel dosimeters and the readings from the control badges were subtracted from the dosimeter to obtain a net reading for determining exposure, ambient external dose should not be included in dose reconstruction after this time. Before the institution of universal badging in April 1957 for those employees who were not monitored, coworker doses should be assigned based on the values in ORAUT (2007b, Table 6-11) and no additional ambient dose should be assigned. Based on a review of the dosimetry literature of the site, no change in the handling of dosimeters occurred when universal badging was introduced; therefore, ambient dose is considered to be appropriately included in the coworker doses.

External ambient doses for each year are available in ORAUT (2006) and can be used for workers who have continuous employment but nonexistent or incomplete monitoring records. For example, EG&G employees were likely stationed in Las Vegas and received dosimeters when they traveled to NTS. If the employee's location cannot be clearly identified, it might be appropriate to assign ambient dose for intervals with no dosimeter exchanges. This would be favorable to the claimant, but the assignment of ambient dose is not a requirement. A second example includes REECo employees who were processed as new employees through NTS (Mercury) and assigned to work at Tonopah Test Range (TTR). These employees have a minimum of one NTS dosimeter. Often no additional records are provided for these employees by Sandia National Laboratory, the responsible organization for dosimetry at TTR. For these REECo employees assigned at TTR, ambient dose from NTS can be assigned as appropriate.

4.5.2 Assigning Internal Ambient Dose

With the exception of cases that can be worked using the bounding assumptions provided by ORAUT-OTIB-0002 (ORAUT 2007d) or ORAUT-OTIB-0018 (ORAUT 2005), environmental inhalation and ingestion intakes presented in Tables 4-7 and 4-11, respectively, shall be applied for all cases. In addition, for applicable years of employment and affected organs, the annual doses provided in Tables 4-9 and 4-14 shall be applied, as a favorable to claimant assumption, as 30-250 keV photons

to account for dose from inhalation and ingestion of short-lived fission and activation products. These intakes and resultant doses shall be entered into the IREP analysis with a constant distribution because they are considered to be reasonable overestimates of the actual intakes and doses.

4.6 ATTRIBUTIONS AND ANNOTATIONS

Where appropriate in this document, bracketed callouts have been inserted to indicate information, conclusions, and recommendations provided to assist in the process of worker dose reconstruction. These callouts are listed here in the Attributions and Annotations section, with information to identify the source and justification for each associated item. Conventional References, which are provided in the next section of this document, link data, quotations, and other information to documents available for review on the Project's Site Research Database.

- [1] Rollins, Eugene M. Oak Ridge Associated Universities Team. Division Manager. October 2007.
The highest radon concentrations were measured in the G-Tunnel and occurred in fractured tuff. Therefore, with the lack of measured data in the U1a Complex, an assumption favorable to claimants was made that the radon concentrations in the U1a Complex were the same as the highest measured concentrations in the G-Tunnel complex.

A.1 Introduction

With the cessation of atmospheric testing at NTS in 1962, the greatest potential for environmental intakes of radioactive material results from the inhalation of radioactive particles that were resuspended from NTS soils into the atmosphere and from ingestion of soils previously contaminated by atmospheric nuclear weapons tests, reactor tests, and safety tests. The potential inhalation intakes can be estimated from air sampling data in the NTS annual environmental reports (see References section) coupled with extensive soil contamination data from between 1983 and 1991 (McArthur 1983, 1985, 1987, 1988, 1989, 1991). Because the air monitoring data was limited to gross alpha and beta measurements, tritium, and isotopes of plutonium (e.g., ²³⁸Pu, ²³⁹Pu, and ²⁴⁰Pu), inhalation intakes of other relatively long-lived radionuclides that have been identified in the NTS soils (e.g., ²⁴¹Am, ⁶⁰Co, ¹³⁷Cs, ⁹⁰Sr, ¹⁵²Eu, ¹⁵⁴Eu, and ¹⁵⁵Eu) are scaled to those of plutonium based on their relative abundance in NTS soils. Ingestion intakes can also be estimated by assuming consumption of contaminated NTS soils. To ensure that both inhalation and ingestion intakes are not underestimated, the relative abundances of the long-lived radionuclides in NTS soils that were determined from the 1991 soil contamination data (McArthur 1991) were decay-corrected to 1963. In addition, to ensure that intakes and resultant doses are not underestimated, correction factors are developed to account for potential exposures to short-lived fission and activation products based on test-specific data from Hicks (1981a,b,c,d). In addition, a correction factor is developed for inhalation intakes which accounts for the phenomenon of early resuspension (Anspaugh 2002).

This approach has been developed to address the unique character of NTS, which is a large outdoor testing facility where potential exposure to radioactive materials was primarily based on residual contamination from atmospheric testing. For most of the employees of the primary contractor,

ATTACHMENT A**AMBIENT ENVIRONMENTAL INTAKES AT THE NEVADA TEST SITE
BASED ON AIR SAMPLING AND SOIL CONTAMINATION DATA**

Page 3 of 27

occupational internal doses can be equated to the doses they potentially received from the resuspension of residual radioactivity from the atmospheric testing (i.e., environmental internal dose). For workers who were primarily indoors (cafeterias, administrative facilities, and maintenance shops) this dose likely represents an overestimate of internal exposure. The environmental internal dose is the occupational internal dose, regardless of the recorded external dose. If an internal exposure was suspected, bioassay was performed. Managing radioactive material in the form of devices was episodic and limited to a few workers (e.g., radiation safety and industrial hygiene personnel, miners, and experimenters). These workers are identified on the rosters that were published before the event, and these workers likely have bioassay results included in the DOE records.

Section A.2 presents air sampling data from the NTS annual environmental reports from 1971 through 2001 and the calculated annual inhalation ^{239}Pu intakes. Section A.3 presents an area-specific summary of NTS soil contamination data that was gathered and reduced in the late 1980s (McArthur 1991). This section also presents soil contamination data that is decay-corrected to 1963. Section A.4 describes the methods that were used to develop inhalation intake scaling factors for radionuclides identified in NTS soils in comparison with intakes of plutonium that were calculated from air sampling data. Section A.5 describes the method that was used to account for higher air concentrations due to resuspension for 1963 (the first year after suspension of atmospheric testing). Section A.6 describes the methods that were used to develop the correction factors that were used to account for organ dose from inhalation of short-lived radionuclides that no longer persist in the NTS environment in measurable quantities. Section A.7 presents the methodology that was used to calculate ingestion intakes from oral consumption of contaminated NTS soils. In addition, Section A.7 provides the methodology that was used to account for ingestion dose from short-lived fission and activation products. Section A.8 includes step-by-step instructions to the dose reconstructor for application of ambient environmental inhalation and ingestion intakes. Attachment B provides a discussion that includes the results of 30 years of inhalation and ingestion intakes in Sections A.6 and A.7.

A.2 Air Sampling Data and Intake Estimates

Routine isotopic atmospheric measurements of plutonium at NTS began in 1971 with samplers in 15 locations across the site. Six additional sampling stations were added in 1978. Equipment at fixed locations continuously sampled the ambient air to monitor for radioactive materials. These locations were chosen to provide representative samples from the populated areas on the site as well as to monitor resuspension of low-fired plutonium spread by safety experiments before 1960 in Areas 2, 3, 4, 7, 9, and 10. Access, worker population, geographical coverage, presence of radioactivity, and availability of electric power were considerations in the site selection for air samplers (Black and Townsend 1997).

In 1988, efforts to monitor radioactive air emissions at NTS were increased as a result of the requirements of DOE Order 5400.1. Known and potential effluent sources throughout NTS were assessed for their potential to contribute to public dose (Black and Townsend 1997).

The ^{239}Pu concentrations in Table A-1 for 1989 through 2001 represent the average of the maximum concentrations for a given area in a given year. In cases where maximum values were not provided (i.e., 1971 through 1988), the average of the average concentrations was reported. In addition to the annual area concentrations, Table A-1 also provides NTS site average and maximum concentrations, which represent the arithmetic averages of the concentration of all the areas and the maximum of the

ATTACHMENT A
AMBIENT ENVIRONMENTAL INTAKES AT THE NEVADA TEST SITE
BASED ON AIR SAMPLING AND SOIL CONTAMINATION DATA
 Page 4 of 27

area maximum or area averages of all the areas, respectively. Potential intakes associated with these concentrations can be calculated under the assumption that an unmonitored worker was occupationally exposed for 2,000 hr/yr with a breathing rate of 2,400 m³/yr. Table A-2 presents these calculated intakes.

- a. Source: NTS Environmental Reports in References section.
- b. Values represent the arithmetic average of the area average concentrations for years 1971 through 1988 and the arithmetic average of the area maximum concentrations for years 1989 through 2001.
- c. Values represent the maximum of the average area concentrations for years 1971 through 1988 and the maximum of the maximum area concentrations for years 1989 through 2001.

Table A-2. Annual inhalation intakes from ²³⁹Pu for sampled areas (Bq).

It should be noted that some covered employees remained on the site continuously for weeks at a time. However, because most of the nonworking hours were spent indoors where ambient air particulate loadings would be much less than the outdoor loadings and because of the conservative assumptions that were used to estimate the values in Table A-2, adjustment of the tabular data is not required to ensure intakes are not underestimated for these individuals. In addition, employees who lived on the site during their work week would have been housed in Area 12 or Area 23 (Mercury). For most years the values in Table A-1 for these locations are less than the site average values.

It is assumed that plutonium could be any of absorption Type S, Super S, or M dependent on which type delivers the maximum organ dose.

A.3 Soil Contamination and Decay Corrections

Extensive studies were performed in the 1980s to quantify residual contamination at NTS (McArthur 1983, 1985, 1987, 1988, 1989, 1991). Table A-3 lists the results of these studies (McArthur 1991). Table A-4 lists the total areal depositions based on the inventory values in Table A-3 divided by the respective areal size. It should be noted that the results shown in Table A-4 are representative of areas of the NTS that have been shown to contain measurable levels of contamination. These area actually represent only about one third of the total area within the boundaries of the NTS.

Because the data shown in Table A-3 is representative of the soil contamination in 1991, these values were decay-corrected to the beginning of 1963 – the first year after the cessation of atmospheric testing. Table A-5 presents the decay-corrected areal soil deposition.

A.4 Scaling Factors for Inhalation Intake Estimates

Because the air sampling program did not provide isotopic analyses for all of the identified radionuclides in NTS soils, scaling factors were developed to estimate potential intakes for these radionuclides based on the relative abundances of these radionuclides in comparison with ²³⁹Pu with soil contamination data (McArthur 1991) decay-corrected to 1963. These area-specific ratios are provided in Table A-6.

The scaling factors in Table A-6 were used in conjunction with the ²³⁹Pu intakes in Table A-2 to determine the potential environmental intakes of all the radionuclides important to dose (Table A-6) that have been identified as persistent in NTS soils. For purposes of dose reconstruction, maximum intakes of these radionuclides were calculated by selecting the maximum annual intake of plutonium (i.e., 0.4131 Bq/yr derived for Area 9 in 1972) and multiplying this value by the maximum scaling factor for each of the radionuclides in Table A-6.

A.5 Correction for Resuspension for Early Times After Atmospheric Tests

Anspaugh (2002) stated that, based on empirical observations, concentration of resuspended radionuclides in air have been noted to display a strong time dependence at early times after deposition and that this pathway might be important for reoccupation of contaminated property. He goes on to state that there has not been universal agreement that resuspension is an important pathway but that it is now generally accepted that there are a few instances where the pathway could be the dominant one. Many observations have shown that the rate of resuspension decreases rapidly with time, and that for accident situations resuspension is only of importance (in comparison with the inhalation exposure from the initial cloud passage) over short periods. For this reason, Anspaugh (2002) states that the resuspension factor model has been widely used to predict the concentration of

resuspended radionuclides at early times after initial deposition while the mass loading model (which uses measurements of dust loading in air and soil contamination data to predict air concentration of

radionuclides) has generally been preferred for times long after deposition. However, Anspaugh also states that it is always preferable to rely on actual measurements that are performed over long periods (such as those in Section A.2 of this report).

Anspaugh (2002) presents several resuspension models that have been proposed but concludes that they can be over- or under-predictive at various times after deposition in comparison with empirical observations. However, with expanded datasets from Hicks (1981e) and others in the 1980s, Anspaugh has proposed a resuspension model that more accurately describes the observed results over the entire time span of the expanded dataset for the NTS:

$$S_f = [10^{-5} e^{-0.07t} + 6 \times 10^{-9} e^{-0.003t} + 10^{-9}] \times 10^{\pm 1} \quad (\text{A-1})$$

A graphical depiction of Equation A-1 is provided in Figure A-1 from time t equal zero to 1,000 d after detonation. As Figure A-1 shows, the resuspension factor S_f ranges from about 10^{-5} at times early after deposition, falls rapidly during the first 100 or so days to a value of about 10^{-8} , and then approaches a value of 10^{-9} after a few years. The factor of 10 at the end of the equation is a statement of uncertainty in the model. If it is true that the mass loading approach is more predictive at times long after initial deposition and that the resuspension proposed by Anspaugh (2002) is predictive of the observed results over the expanded dataset (including those that were developed in the 1980s), then the factor of 10^{-9} could be taken to be the resuspension factor that would be predictive of the mass loading process that is thought to be more important during the times when the

ATTACHMENT A
AMBIENT ENVIRONMENTAL INTAKES AT THE NEVADA TEST SITE
BASED ON AIR SAMPLING AND SOIL CONTAMINATION DATA
 Page 10 of 27

air monitoring data are available (i.e., 1971 through 2001, see Section A.2). When Anspaugh's proposed resuspension model (i.e., Equation A-1) is integrated from 180 to 545 days and compared to the result of the integral of the constant 10^{-9} over the same period, a factor is developed that can be used to correct the intakes that are derived from air sampling data (i.e., times long after initial deposition) for the early resuspension phenomenon that has been observed at NTS. The period of integration was selected to begin at day 180 because the last atmospheric tests at NTS were in July of 1962 and therefore about 180 days had passed before the beginning of 1963 (the starting date for reconstruction of internal dose at NTS in the absence of bioassay results for the employee). For the Anspaugh model, the early resuspension correction factor has been determined to be 3.12. In a similar manner, correction factors for 1964 and 1965 were determined to be 1.72 and 1.24, respectively. Therefore, for dose reconstruction purposes, the scaled maximum inhalation intakes in Table A-6 should be multiplied by these factors to account for early resuspension from 1963 through 1965. These resultant intakes are shown in Table A-7. If necessary, these intakes can be prorated for time less than a year for a best estimate if the worker was on the site for only a fraction of the year.

Figure A-1. Resuspension factor as a function of time after initial deposition.

A.6 Corrections for Inhalation Dose From Short-lived Fission and Activation Products

During the early and mid-1960s, workers could have been exposed to fallout from atmospheric testing that contained short-lived fission and activation products (e.g., ^{144}Ce , ^{106}Ru , etc.) that have not persisted in NTS soils in measurable quantities. For purposes of dose reconstruction, two methods are described to account for possible exposure to these radionuclides.

Potential inhalation dose from short-lived fission and activation products can be estimated using data that were developed by Hicks (1981e). Hicks (1981e) provides estimates of ground deposition of 152 fission products and 25 neutron-induced nuclides from nuclear weapons tests. The data for these calculations were for the last atmospheric tests NTS conducted in 1962 as a function of time after detonation. Spreadsheets were developed to multiply the relative abundance of each of these radionuclides by its associated International Commission on Radiological Protection (ICRP) Publication 68 (ICRP 1995) inhalation organ dose conversion factor (Bunker 1999) to determine the relative importance of each of the 177 radionuclides to total organ dose. Except for ^{90}Sr , the inhalation dose conversion factors were those for the absorption type (i.e., S, M, or F) that produced the largest dose to the organ of interest. For ^{90}Sr , only absorption Type F was used. In addition, because the Publication 68 organ dose factors represent the 50-yr committed dose, the IMBA computer program was used to develop the annual organ-specific dose conversion factor for ^{241}Am , which was used in the calculations to better represent the relative importance ^{241}Am , which delivers dose to the affected organ over long periods of time. Similarly, annual organ-specific dose conversion factors were developed for ^{90}Sr to provide a more accurate time-dependant correction factor.

The development of the short-lived fission and activation product correction factors based on the Hicks data must be adjusted for fractionation. Fractionation is a phenomenon due to both chemical and physical separation of the radionuclides in the fireball in first few minutes after detonation. Within the first minute after detonation, the vaporized soil components condense with other refractory elements and begin to fall to the surface. The volatile elements (except for krypton and xenon) and their progeny condense in 6 to 8 minutes and begin falling to the surface (Hicks 1981e). Because the Hicks data was developed to estimate offsite levels of fallout and resultant dose, fractionation effects were simulated in the Hicks data by the removal of a fraction of the refractory nuclides from the calculated abundances. In general, air drops were assumed to be unfractionated and offsite fallout from surface and cratering tests was assumed to have 0.4 of the refractory elements. For all other types of tests, offsite fallout was assumed to have 0.5 of the refractory elements present. Therefore, the refractory elements (e.g., beryllium, sodium, manganese, iron, cobalt, copper, yttrium, zirconium, niobium, barium, rare earths, thorium, uranium, neptunium, plutonium, americium, and curium) in the Hicks data must be adjusted to produce the best estimate of their enriched abundances in the onsite environment to which the workers could have been exposed. Adjustment factors for each radionuclide were determined from data in Hicks (1984). This report provided relative abundances of radionuclides assuming no fraction, 50% fraction, and 90% fraction of refractory elements. From these data, ratios were developed for the 50%-fractionation case (Table A-8). These ratios were used to deplete the refractory elements in the far-field (i.e., offsite) environment to estimate doses to offsite individuals. Therefore, to enrich the near-field (i.e., onsite) environment, the inverse of these ratios was applied to the Hicks Small Boy data (see below). These inverse ratios were applied twice because the Hicks Small Boy data was provided to estimate fallout in the offsite environment. The first application results in the data that represent no fractionation while the second application results in data that is enriched with refractory elements.

In Table A-8, the radionuclides with ratios less than 1.0 represent the radionuclides that are considered to condense as refractory elements while the radionuclides with ratios greater than 1.0 are assumed to behave as volatile elements. It should be noted that although strontium is considered to be a refractory element, for purposes of these calculation, the assumption is made that it behaves like a volatile element because its fission precursors are noble gases (i.e., volatile elements).

Table A-8. Far-field refractory enrichment ratios.

The fission and activation product correction factor was developed based on the relative contribution of ⁹⁰Sr to total organ dose. Strontium-90 was chosen because Hicks provided time-dependant abundances for this radionuclide and ⁹⁰Sr continues to persist in the NTS environment. Therefore, by determining the relative importance of organ dose from ⁹⁰Sr to the total dose from all 177 radionuclides, a multiplication factor was developed, by which the various organ doses from the ⁹⁰Sr intakes (Table A-7) can be multiplied, to account for short-lived fission and activation products. For example, using the Hicks data for Storax Small Boy, which was the next-to-last atmospheric test at NTS on July 14, 1962 (Storax Little Feller I was the last atmospheric test on July 17, 1962), it was determined that the relative importance of ⁹⁰Sr dose to the lung to the total dose from all 177 radionuclides varied, in a mostly linear fashion, from 0.00284 to 0.0589 from 1 to 365 days after detonation, respectively (see Figure A-2). Using the trend line function, an expression for the relative importance of ⁹⁰Sr dose y to total dose as a function of the number of days after detonation x was developed:

$$y = 0.0001x + 0.0074 \quad (A-2)$$

 Page 13 of 27

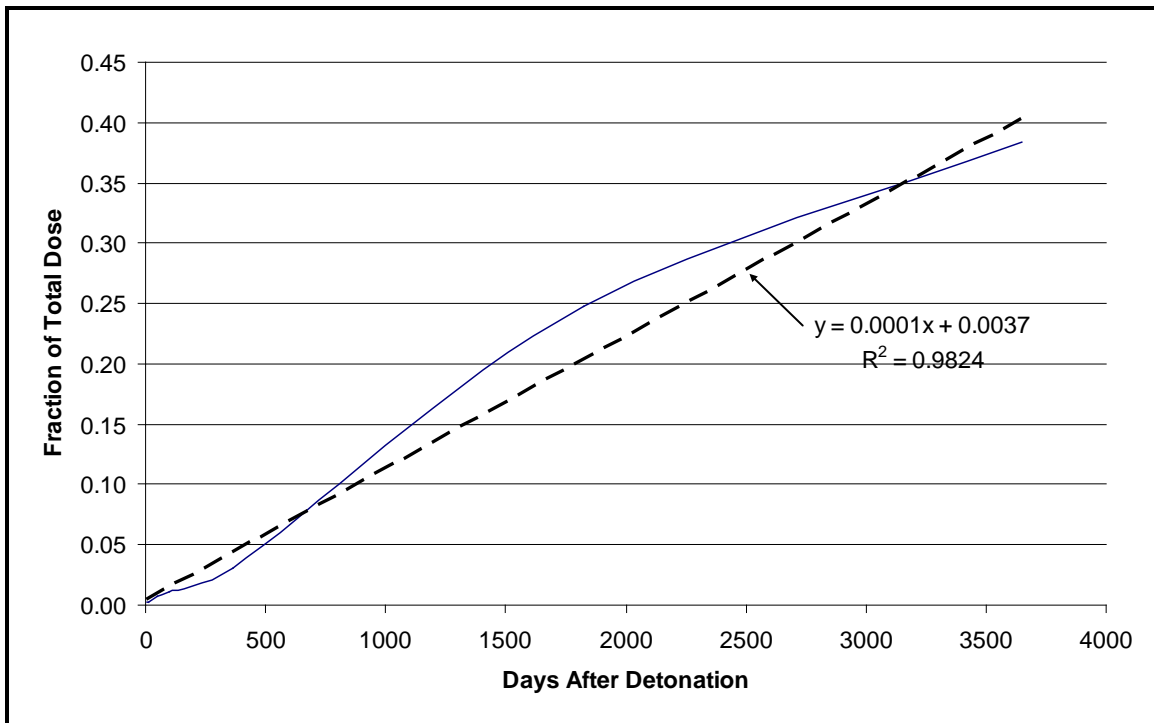

Figure A-2. Small Boy – ^{90}Sr fraction of total dose lungs.

To ensure favorability to claimants, the relative importance of ^{90}Sr lung dose to the total lung dose from all fission and activation products was examined for several tests including Teapot Turk in 1955 and Little Feller I in 1962 (Hicks 1981a,b,c,d). The slope of the trend lines that predict the relative importance of ^{90}Sr dose was determined to be $0.0001x$ for Storax Small Boy, $0.0002x$ for Storax Little Feller I (Figure A-3) Teapot Turk (see Figure A-4). Because the slope of the trend line is directly proportional to the relative importance of the ^{90}Sr dose to total dose (i.e., the larger the slope, the larger the relative importance of ^{90}Sr dose), the tests with the smallest slopes result in the highest multiplicative correction factors for fission and activation products. Therefore, to ensure the organ dose from short-lived fission and activation products is not underestimated, the Hicks data for the Storax Small Boy test was selected to be used to determine the fission and activation product dose correction factor. This assumption is also justified by the fact that the test was very near the last atmospheric test (i.e., Storax Little Feller I) and would therefore have been the test most likely to produce the short-lived fission and activation product intakes for workers at NTS after 1962 (the period of time for which organ dose from environmental intakes is calculated).

Integrating Equation A-2 for Small Boy from 0 to 365 d and dividing the result by 365 (the value that represents the integrated total dose for 1 yr), it was determined that for the first year after detonation the lung dose from ^{90}Sr represented 0.0000738 or about 0.00738% of the dose from all 177 radionuclides. Therefore, the inverse of the value would produce a factor of 13,600 that the lung dose from the ^{90}Sr intake (Table A-7) could be multiplied by to account for inhalation dose from short-lived fission and activation products. Similar integrations were performed for subsequent years through 1972.

Correction factors to account for inhalation intakes of short-lived fission and activation products have been developed for all organs using the Hicks data for Storax Small Boy (Table A-9). These correction factors were based on the relationships that Figures A-5 through A-11 show.

The IMBA computer program was used to determine the organ doses from the scaled intakes provided in Table A-7 for a period of 10 yr. These doses were then multiplied by the correction factors in Table A-9 to determine the additional dose that should be added to account for potential dose from inhalation of short-lived fission and activation products. The organ-specific fission and activation doses are provided in Table A-10.

The application of the early fission and activation product correction factor through 1972 intakes is favorable to claimants because the Hicks data verifies that after 10 years, over 90% of the total organ dose for all organs is delivered by ²⁴¹Am, ¹³⁷Cs, and/or ⁹⁰Sr. Further, as times after detonation become greater, the relative importance of ²⁴¹Am, ¹³⁷Cs, and ⁹⁰Sr become greater and, because the organ doses from these radionuclides are already accounted for by the scaled intakes (Table A-7), the dose from these radionuclides is doubled.

A.7 Ingestion Pathway

To account for potential intakes from inadvertent ingestion of contaminated soil, the area-specific radionuclide soil deposition data in Table A-5 were converted to volumetric data (i.e., Bq/mg) by assuming a radionuclide relaxation depth of 2.3 cm (DOE 2003) and a soil density of 1.5 g/cm³ (DOE 2003). The area-specific radionuclide soil concentrations are presented in Table A-11.

If the assumption is made that the workers ingested 100 mg of soil each day, which is favorable to claimants (EPA [1989] recommends a value of 50 mg/d), and the assumption is made that full-time employment was 250 d/yr, annual ingestion can be calculated. The area-specific annual ingestion rates are shown in Table A-12.

Page 21 of 27

It should be noted that for most radionuclides, Area 30 provided the highest areal deposition and resultant intakes. Area 30 is relatively small (150 km²), inaccessible, and is located on the Western edge of NTS. It has rugged terrain and includes the northern reaches of Fortymile Canyon. In 1968, it was the site of Project BUGGY, the first nuclear row-charge experiment in the PLOWSHARE Program. As a result of the test, a trench 255 m long, 77 m wide, and 206 m deep was created. The test resulted in large quantities of vitrified glass. Because of the bias that is introduced when Area 30 is included, the maximum annual intakes in Table A-12 have been provided with Area 30 areal concentrations excluded. The Area 30 intakes should only be used if it can be determined that the worker was assigned to and primarily worked in Area 30.

To determine the relative importance of the ingestion pathway, a hypothetical ingestion scenario was used that assumed 30 years of the Table A-12 maximum intakes and used the IMBA computer program to determine organ doses from these intakes. The annual organ doses from ingestion of ^{238,239}Pu and ²⁴¹Am greater than 0.001 rem are presented in Table A-13. With the exception of the red bone marrow and bone surfaces, the annual doses from the Table A-12 maximum ingestion rates of ⁶⁰Co, ¹³⁷Cs, and ^{152,154,155}Eu were all less than 0.001 rem. For the red bone marrow and bone surfaces, the annual doses were all less than 0.002 rem.

Similar to what was done for inhalation intakes discussed in Section A.5 of this report, ingestion doses need to be adjusted for potential dose from short-lived fission and activation products that are no longer persistent in NTS soils in measurable amounts. The organ-specific fission and activation product correction factors were again developed (for the reasons that are provided in Section A.5) based on the relative contribution of ⁹⁰Sr to the total ingestion dose using the Hicks [1981c] data from the Storax Small Boy test in July of 1962. As was done in Section A.5 for inhalation dose, organ-specific relationships were developed for the ⁹⁰Sr fraction of total dose. These relationships are provided in Figures A-12 through A-17. With the exception of fractional dose to bone surfaces and red bone marrow, these relationships were valid out to 10 years after detonation. For bone surfaces and red bone marrow, the time dependant relationships were determined for the first year and for the last 9 years.

To account for fractionation, the refractory elements included in the Storax Small Boy Hicks data were multiplied by a factor of 2. Increasing the abundance of the refractory elements provides a more reasonable estimate of their relative contribution to total dose. As was done for the inhalation correction factors, these radionuclide- and time-dependant relative abundances are then multiplied by their organ-specific ingestion dose conversion factors (Bunker 1999) to determine the radionuclide-specific, relative importance to total dose as a function of time after detonation. It should be noted that because of the large difference between the 50-year committed dose conversion factor and the annual dose conversion factor for ²⁴¹Am, the IMBA computer program was used to calculate the annual ingestion dose conversion factors which were then used instead of the 50-yr committed dose conversion factors. The same method was also used for ⁹⁰Sr annual dose conversion factors. To ensure that organ doses were not underestimated, the f1 factor for each radionuclide was chosen to provide the largest dose to the specific organ of interest.

It should be noted that the ingestion correction factors were evaluated over a 10-yr period. This is due to the fact that ¹⁴⁴Ce and ¹⁰⁶Ru continue to provide relatively large ingestion doses through 5 years after detonation. Therefore, to capture their contributions to total dose, the correction factor integration times were extended to 10 years where the relative contribution of ¹⁴⁴Ce and ¹⁰⁶Ru to total dose was less than three percent for all organs. Also, at the end of 10 years, over 95% of the total

ingestion dose is delivered by ⁹⁰Sr and ¹³⁷Cs; their dose accounted for by the ingestion intakes in Table A-12.

Using the relationships shown in Figures A-12 through A-17, short-lived fission and activation ingestion correction factors were developed (Table A-14). As with the inhalation fission and activation factors, these correction factors are multiplied by the organ-specific ⁹⁰Sr annual doses (from the intakes in Table A-12 [i.e., 55.42 Bq/yr]) to calculate additional ingestion dose from short-lived fission and products.

Table A-14. Organ-specific ingestion fission and activation correction factors.

To simplify the application of organ-specific ingestion dose from short-lived fission and activation products, the IMBA computer program was used to determine the organ specific annual doses for the ⁹⁰Sr intake of 55.42 Bq/yr for 1963 through 1972 (Table A-15). These doses are then multiplied by the Table A-14 organ-specific correction factors to provide the annual doses from ingestion of short-lived fission and activation products (Table A-16).

Table A-15. Organ-specific annual ingestion doses (rem) for the ⁹⁰Sr intake of 55.42 Bq/yr.

A.8 Instruction to Dose Reconstructors for Assignment of Environmental Intakes

With the exception of cases that can be worked with the use of the bounding assumptions from ORAUT-OTIB-0002 (ORAUT 2007d) or ORAUT-OTIB-0018 (ORAUT 2005), environmental inhalation and ingestion intakes in Tables A-7 and A-12, respectively, should be applied for all cases. In addition, for applicable years of employment and affected organs, the annual doses from 30- to 250-keV photons in Tables A-10 and A-16 should be applied to account for dose from inhalation and ingestion of short-lived fission and activation products. These intakes and resultant doses should be entered into the IREP analysis with a constant distribution because they are considered to be reasonable overestimates of the actual intakes and doses.

ATTACHMENT B
TOTAL ANNUAL ORGAN DOSES FROM 30 YEARS OF INHALATION AND INGESTION INTAKES
AND SOURCES OF OVERESTIMATED ORGAN DOSE

Page 1 of 4

In the previous sections, methods were presented to account for organ dose from ambient environmental inhalation and ingestion intakes of radioactive materials in NTS atmosphere and soils. To illustrate the importance of these pathways, the IMBA computer program was used to determine organ doses from 30 years of the inhalation intakes in Table A-7 and the ingestion intakes in Table A-12. These 30-year organ doses and the fractional contribution for each of the radionuclides persistent in the NTS soils are presented in Table B-1. To correct for exposure to short-lived fission and activation, the dose reconstructor should add annual doses that were greater than 0.001 rem from Tables A-10 and A-16 as 30- to 250-keV photons with a constant distribution.

ATTACHMENT B
TOTAL ANNUAL ORGAN DOSES FROM 30 YEARS OF INHALATION AND INGESTION INTAKES
AND SOURCES OF OVERESTIMATED ORGAN DOSE

Page 2 of 4

Table B-1. Total annual organ doses greater than 0.0001 rem from 30 years of inhalation and ingestion intakes (rem).
