## Detailed life tables, 1949-51

This report contains detailed life tables for the United States, 1949-51. They are the most recent in a series of life tables that have been prepared at 10-year intervals for the death-registration States, which originated with those for 1900-1902. Each of the tables in the series is based on a census of population and deaths in a 3-year period containing the census year. The life tables in this report are based on the 1950 census of population and deaths of the 3-year period 1949-51 for the entire continental United States. In deriving life table values at ages under 5, use was made, also, of reported births for each of the 8 years 1944 to 1951, and of deaths for the same years. Nine detailed life tables are contained in this report. Life tables are given for whites and nonwhites, separately by sex, and for both sexes combined, and also for the total population and for total males and total females.

The accuracy of the life table values for 1949-51 probably compares favorably with the accuracy of the statistics on which they are based. However, it is well known that the basic statistics are subject to various errors, the magnitude of which is usually difficult to estimate precisely. Prior to the calculation of the values of the life tables, the more serious errors were examined carefully, and the basic data were adjusted to remove errors when corrections were available or could be derived. It should be noted that the population and mortality statistics at the oldest ages were least trustworthy. Special methods were devised to determine the proportions dying at ages over 87 for nonwhites and at ages over 92 for whites. Therefore, the life table values at the oldest ages are more likely to contain errors than those at other ages, and, in fact, they may not necessarily represent actual conditions.

A later publication will contain a complete statement of the adjustments made in the basic data and of the methods and formulas by which the life tables were prepared.

## Life table values, 1949-51

The rates of mortality during a specific period may be summarized by the life table method to obtain measures of comparative longevity. The basis of

these measures is a closed cohort for each of the population groups under examination which is assumed to be subject throughout life to the mortality rates of that period. For example, table 1 presents a life table for the total population showing the progress of a cohort starting with 100,000 live births and subject throughout life to the average mortality rates for the 3-year period 1949-51.

The customary measure of the comparative longevity of different populations is the average duration of life, also called the expectation of life at birth. This is the average number of years lived by the members of the life table cohort. In each of the tables, the average duration of life appears opposite age 0 in the column which gives the average remaining lifetime. These values indicate that females, on the average, live longer than males, and white persons longer than nonwhite. The expectation of life at birth is 66.31 years for white males, 72.03 years for white females, 58.91 years for nonwhite males, and 62.70 years for nonwhite females.

There is, however, some objection to the use of the average duration of life as a standard of comparison because the method of calculating it gives great weight to the relatively large number of deaths occurring in the first year of life. This influence may be entirely eliminated by considering instead the average lifetime remaining to those members of the cohort surviving to age 1, or, in other words, the expectation of life at age 1. As a result of this change, the differences between these various groups are somewhat reduced. Nevertheless, during 1949-51 white females still live, on the average, 5.36 years longer than white males, and 8.40 years longer than nonwhite females, while white males live 6.35 years longer than nonwhite males.

Another possible standard for comparing the longevity of different populations is provided by the median length of life, or "probable lifetime," which is the age at which half of the original members of the cohort have died. When the life table cohort starts with 100,000 births, this would be the age at which there are just 50,000 survivors. In other words, it is the age to which an infant born alive has just an even chance of surviving. In computing this median length of life, the deaths in the age groups in which the median age lies are assumed to be evenly distributed. Thus, the median length of life on the basis of 1949-51

mortality rates for white males is determined to be 70.67 years; for white females, 76.41 years; for nonwhite males, 62.69 years; and for nonwhite females, 66.21 years. It is evident that the median length of life is longer than the average duration of life for all groups.

Still another measure of comparative longevity is the number of persons surviving to stated ages in a cohort, of, say, 100,000 live births. For example, it is of some interest to examine the proportions of survivors to ages 21 and 65, since these ages may be taken as representing, respectively, the attainment of manhood or womanhood, and the retirement age prescribed by the Social Security Act. At age 21, the ratio of nonwhite to white survivors in the 1949-51 life tables is 97 percent, and at age 65 the ratio is 70 percent. This marked difference indicates the cumulative effect of higher mortality among nonwhites in the intervening ages. The corresponding ratios of males to females are 98 percent and 83 percent.

#### Trend of life table values for 1900-1951

Selected life table values for five decennial life tables covering the period 1900 to 1951 are given in tables 10-12, by race and sex. In using these tables it must be remembered that values for earlier periods are not strictly comparable with those for later periods. The area covered at each period was limited by the number of death-registration States, and values for periods prior to 1929-31 do not cover the entire continental United States. Neither do the values for periods prior to 1949-51 cover all nonwhites, but are limited to Negroes only. It should be remembered, also, that there has been progressive improvement in the completeness of death reporting during

this period.

It seems unlikely that variations in the scope of the life tables from period to period would seriously bias the major trends in the values for 1900-1951. However, it is believed that the fluctuations shown at certain ages in the values for Negroes during the first 30 years of the century may be attributable, in part, to the expanding character of the death-registration area, and, in part, to progressive improvement in the completeness of death reporting.

During the first half of this century, there was a spectacular improvement in the expectation of life for all four subdivisions of the population by race and sex. The improvement in longevity has been appreciably greater for females than for males, and for nonwhites than for whites. The relative improvement in the longevity of females is particularly striking because it has increased the disparity in the expectation of life between the sexes. The average duration of life (table 12) has increased by 18.08 years for white males, 20.95 years for white females, 26.37 years for nonwhite males, and 27.66 years for nonwhite females. The proportion dying during the first year of life (table 10) has decreased by 77 percent for white males, 79 percent for white females, 80 percent for nonwhite males, and 81 percent for nonwhite females. The number attaining age 65 in a life table cohort of 100,000 live births (table 11) has increased by 24,296 for white males, by 32,967 for white females, by 26,183 for nonwhite males, and by 30,363 for nonwhite females. For all four subdivisions of the population, the improvement in the average remaining lifetime becomes progressively less at older ages, but recent values even at relatively old ages are substantially higher than in 1900-1902.

#### EXPLANATION OF THE COLUMNS OF THE LIFE TABLE

Both the descriptive titles and the conventional actuarial symbols appear at the head of the columns in each of the tables. The description which follows gives a more detailed explanation of the seven columns of the life table.

*Column 1—Year of age ( $x$  to  $x + 1$ ).*—The year of age, shown in column 1, is the interval between the two exact ages indicated. For instance, "21-22" indicates the interval between the twenty-first birthday and the twenty-second, in other words, the twenty-second year of life.

*Column 2—Proportion dying ( $q_x$ ).*—This column shows the proportion dying within 1 year after the birthday indicated among those alive on that birthday. For example, the proportion dying in the age interval 21-22 for white males is .00169. In other words, during 1949-51, out of every 1,000 white males alive and exactly 21 years old, 1.69 would die before reaching their twenty-second birthday. The "proportion

dying" column forms the basis of the life table, all the other columns being derived from it.

*Column 3—Number living ( $l_x$ ).*—This column shows the number of persons who survive to each age out of a cohort of 100,000 live births, among whom the proportions dying in each age throughout their lives are exactly those shown in column 2. Thus, out of 100,000 white male babies born alive, 96,931 will complete the first year of life and enter the second; 96,726 will begin the third year; 94,950 will reach age 21; and 38,104 will live to age 75.

*Column 4—Number dying ( $d_x$ ).*—This column shows the number dying in each successive year of age out of 100,000 live births. Out of 100,000 white males born alive, 3,069 die in the first year of life, 205 in the second year, 161 in the twenty-second year, and 2,858 in the seventy-sixth year. Each figure in column 4 is the difference between two successive figures in column 3.

*Columns 5 and 6—Stationary population ( $L_x$  and  $T_x$ ).*—Suppose that a group of 100,000 individuals like that assumed in columns 3 and 4 is born every year, and that the proportions dying in each such group in each year of life throughout the lives of the members are exactly those shown in column 2. If there were no migration and if the births were evenly distributed over the calendar year, the survivors of these births would make up what is called a stationary population—stationary because in such a population the number of persons living in any given year of age would never change. When an individual left an age, either by death or by growing older and entering the next higher age, his place would immediately be taken by some one entering from the next lower age. Thus, a census taken at any time in such a stationary community would always show the same total population and the same numerical distribution of that population among the various ages. In such a stationary population supported by 100,000 annual births, column 3 shows the number of persons who, each year, reach the birthday indicated in column 1, while column 4 shows the number of persons who die each year in the indicated age interval.

Column 5,  $L_x$ , shows the number of persons in the stationary population in the indicated age interval. For example, the figure given for white males in the year of life 21-22 is 94,869. This means that in a stationary population of white males supported by 100,000 annual births and with proportions dying in each age group always in accordance with column 2, a census taken on any date would show 94,869 persons between 21 and 22 years old.

Column 6,  $T_x$ , shows the total number of persons in the stationary population (column 5) in the indicated age interval and all subsequent age intervals. For example, in the stationary population of white males referred to in the last illustration, column 6 shows that there would be at any given moment a total of 4,614,719 persons who have passed their twenty-first birthday. The population at all ages 0 and above

(in other words, the white male population of the stationary community) would be 6,631,405.

*Column 7—Average remaining lifetime ( $\bar{e}_x$ ).*—The average remaining lifetime (also called the complete expectation of life) at any age is the average number of years remaining to be lived by those surviving to that age, on the basis of a given set of age-specific rates of dying. In order to arrive at this value, it is first necessary to observe that the figures in column 5 of the life tables can also be interpreted in terms of a single life table cohort, without introducing the concept of the stationary population. From this point of view, each figure in column 5 represents the total time (in years) lived between the two indicated birthdays by all those reaching the earlier birthday among the survivors of a cohort of 100,000 live births. Thus, the figure 94,869 for white males in the year of life 21-22 is the total number of years lived between the twenty-first and twenty-second birthdays by the 94,950 (column 3) who reach the twenty-first birthday out of 100,000 white males born alive. The corresponding figure in column 6 (4,614,719) is the total number of years lived after attaining age 21 by the 94,950 reaching that age. This number of years divided by the number of persons (4,614,719 divided by 94,950) gives 48.60 years as the average remaining lifetime of white males at age 21.

Care should be exercised in drawing conclusions from the figures in column 7. Thus, observing that the average lifetime of white persons is greater than that of nonwhite, one should not conclude that the oldest ages reached by white persons necessarily exceed those attained by the most long-lived nonwhite. The difference in the average length of life is due to the fact that a greater proportion of nonwhites die before reaching old age. For example, the number surviving to age 65 out of 100,000 born alive is far greater among white persons than among nonwhite; yet the average length of life remaining at age 65 is about the same for both groups.

## VITAL STATISTICS—SPECIAL REPORTS

TABLE 1. LIFE TABLE FOR THE TOTAL POPULATION: UNITED STATES, 1949-51

<sup>1</sup>Figures for the nonwhite groups cover only Negroes. However, in no case did the Negro population comprise less than 95 percent of the corresponding nonwhite population.

NOTE.—For 1900-1902 and 1909-11, data are for the death-registration States of 1900, which consisted of 10 States and the District of Columbia; for 1919-21, for the death-registration States of 1920, which consisted of 34 States and the District of Columbia; for 1929-31, 1939-41, and 1949-51, for the entire continental United States.

# Actuarial Tables

## Based on United States Life Tables: 1949-51

This report contains certain tables used by actuaries in computing the present values of life annuities and survivor benefits payable on the death of an insured individual.<sup>1</sup>

The actuarial functions included are based on the 1949-51 life tables for white males, white females, nonwhite males, nonwhite females, total males,

<sup>1</sup>For explanation of the uses of these tables, either of the following books may be consulted: Greville, Thomas N. E., "United States Life Tables and Actuarial Tables, 1939-1941," U. S. Government Printing Office, Washington, D. C., 1946; Jordan, C. W., "Life Contingencies," The Society of Actuaries, Chicago, Ill., 1952.

and total females in the United States. The functions tabulated are the commutation columns  $D$ ,  $N$ , and  $H$  and the whole life immediate annuity values (first payment payable after 1 year from the commencement of the annuity). For white males and white females, these are given at five interest rates: 2,  $2\frac{1}{2}$ , 3,  $3\frac{1}{2}$ , and 4 percent. Values for nonwhite males, nonwhite females, total males, and total females are given only for a 3 percent interest rate. In addition, the corresponding values for white males and white females on a continuous basis are given at 3 percent interest.

These tables have been computed in the Division of the Actuary, Social Security Administration.

Life table values, 1949-51-----	56
Trend of infant life table values for 1929-51-----	57
Method of constructing the infant life tables-----	57
Explanation of the columns of the life table for the first year of life-----	62
<b>Text Tables</b>	
<b>Table</b>	
A. Infant mortality rates by race and sex: United States, 1929-31, 1939-41, and 1949-51-----	57
B. Mortality data employed in the computation of probabilities of dying during subdivisions of the first year of life, by race and sex: United States, 1949-51-----	57
C. Natality data employed in the computation of probabilities of dying during subdivisions of the first year of life, by race and sex: United States, 1949-51-----	58
D. Formulas employed in the computation of the number of exposures to the risk of death by subdivisions of the first year of life: United States, 1949-51-----	59
E. Estimates of deaths under 1 day by age, race, and sex: United States, 1949-51-----	61
F. Proportion of deaths under 1 day of age assumed to represent births of the previous day-----	61
G. Values of $t f_o$ for deaths under 1 day by race and sex: United States, 1949-51-----	61
<b>General Tables</b>	
1. Life table for the first year of life, total population: United States, 1949-51-----	63
2. Life tables for the first year of life, by race and sex: United States, 1949-51-----	64
3. Proportion of infants dying during specified age intervals of the first year of life who were alive at the beginning of the age interval, by race and sex: United States, 1929-31, 1939-41, and 1949-51-----	68
4. Number surviving to the beginning of the specified age intervals of the first year of life out of 100,000 born alive, by race and sex: United States, 1929-31, 1939-41, and 1949-51-----	69
5. Average remaining lifetime in years at the beginning of the specified age intervals of the first year of life, by race and sex: United States, 1929-31, 1939-41, and 1949-51-----	70
<b>Figures</b>	
Average remaining lifetime at ages during the first year of life by race and sex: United States, 1949-51 -----	56

# United States Life Tables for the First Year of Life: 1949-51\*

By Monroe G. Sirken, Chief, Actuarial Analysis Section

## Infant life tables, 1949-51

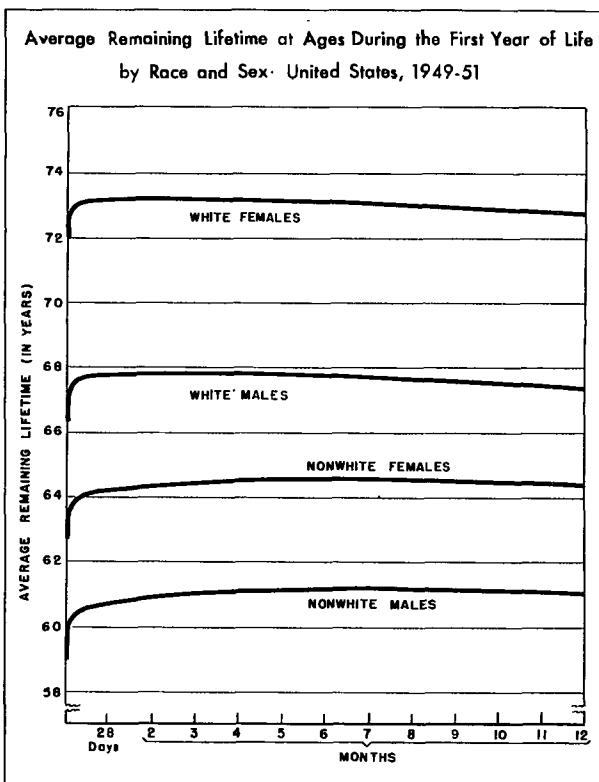

This report is a supplement to the detailed life tables for the United States, 1949-51,<sup>1</sup> which were published previously. Life tables for the first year of life are given for the nine population groups for which detailed life tables were prepared; namely, for white and nonwhite males and females, for total whites and total nonwhites, for total males and total females, and for the total population. The infant life tables contained in this report are based on tabulations of registered deaths by subdivisions of the first year of life for the 3 years from 1949 through 1951, and on tabulations of registered births during the 4 years from 1948 through 1951, which constitute the cohorts of infants in these age intervals during the 3-year period.

## Life table values, 1949-51

The age specific mortality rates for a population group during a particular period may be summarized by the life table method. The basis of the method is a hypothetical closed cohort which is assumed to be subject to these mortality rates. In the detailed life table, a closed cohort of 100,000 births is subject to the prevailing mortality rates for each year of age throughout the lives of the members. However, in the infant life table, a closed cohort is subject to the mortality rates for subdivisions of a year of age, but for the first year of life only. For example, table 1 presents an infant life table for the total population, showing the progress of a cohort starting with 100,000 live births, and subject during subdivisions of the first year of life to the average mortality rates for the 3-year period 1949-51.

The expectation of life is the customary measure of comparative longevity of different populations based on the life table. The expectation of life at a

specified age is the average number of years of life remaining for the members of the life table cohort who attain the age in question. Values of the average remaining lifetime at ages during the first year of life are plotted in the chart for each race-sex group. In each case, the curve rises at a rapid rate during the first few days of life. It continues to rise thereafter, but at a much slower rate until the age at which the maximum value of the expectation of life is attained. Then the curve declines at almost an imperceptible rate for the remainder of the first year of life. The maximum value of the expectation of life is attained in the fourth and fifth months by white males, in the third and fourth months by white females, and in the eighth month of life by nonwhite males and nonwhite females.

\*The author wishes to acknowledge the assistance of Mr. Gustav A. Carlson in the computation of the tables.

<sup>1</sup>National Office of Vital Statistics, "United States Life Tables, 1949-51," Vital Statistics—Special Reports, vol. 41, No. 1, 1954.

Despite substantial increases in the expectation of life in the first year for each race-sex group, the minimum value for females exceeds the maximum value for males, and the minimum value for whites exceeds the maximum value for nonwhites. However, the differences in longevity among the race-sex groups are largest at birth and become smaller with advancing age. Thus, the difference in the expectation of life between white females and nonwhite males is 1.41 years smaller at 1 year of age than at birth.

#### Trend of infant life table values for 1929-51

Selected infant life table values for three decennial life tables covering the period 1929 to 1951 are given in tables 3 to 5, by race and sex. The life tables for these periods are based on data for the entire continental United States. However, the values may not be strictly comparable between periods because the improvement in the completeness of registration of births and of infant deaths by subdivisions of the first year of life has not necessarily occurred at the same rate.

There was a spectacular improvement in longevity for all race-sex groups during the past two decades. The expectation of life at birth increased 7.74 years for white males, 9.89 years for white females, 11.36 years for nonwhite males, and 13.19 years for nonwhite females. The rapid decline in infant mortality rates contributed substantially to the improvement in longevity. Thus, the expectation of life at birth would be about 2.2 years smaller for white males and nonwhite males, and about 2.0 years smaller for white females and nonwhite females than the values shown in the 1949-51 life tables, if the infant mortality rates had not changed since 1929-31. Infant mortality rates, according to life tables for the past three decennial periods, are shown in table A.

The improvement in longevity during the past two decades was greater for females than for males, and greater for nonwhites than for whites. The relative improvement in longevity for the race-sex groups, increased the disparity between the sexes

TABLE A. INFANT MORTALITY RATES BY RACE AND SEX: UNITED STATES, 1929-31, 1939-41, AND 1949-51

(Deaths under 1 year per 1,000 live births in each race-sex group)

RACE AND SEX	1949-51	1939-41 <sup>1</sup>	1929-31 <sup>1</sup>
White males-----	30.69	48.12	62.32
White females-----	23.55	37.89	49.63
Nonwhite males-----	50.89	82.28	87.32
Nonwhite females-----	40.87	65.84	72.04

<sup>1</sup>Figures for nonwhites refer to Negroes only.

and decreased the disparity between the races in the expectation of life at birth. Nevertheless, the disparity in longevity between the races far exceeds the disparity between the sexes in the 1949-51 infant life tables. It is noteworthy, that nonwhites barely attained an expectation of life at birth in 1949-51 that was reached by whites in 1929-31.

#### Method of constructing the infant life tables

Accuracy of the data.—Tabulations of registered infant deaths and live births in the continental United States were used to prepare the infant life tables in this report. It has been stated that these tables are based on tabulations of registered deaths by subdivisions of the first year of life for the 3 years from 1949 through 1951, and on tabulations of registered live births during the 4 years from 1948 through 1951, which constitute the cohorts of infants in these age intervals during the

<sup>1</sup>Based on a 50-percent sample.

<sup>2</sup>For results of the test, see "Birth Registration Completeness in the United States and Geographic Areas, 1950," by Sam Shapiro and Joseph Schachter, Vital Statistics—Special Reports, vol. 39, No. 2, 1954.

pleness of infant death registration, it was assumed that the reported statistics of births and of deaths during each subdivision of the first year of life, were equally complete. Information on the extent of misstatement of age reported on death certificates of infants is virtually nonexistent. Since the evidence did not indicate too many deaths at some ages and too few at other ages of the first year of life, the infant mortality statistics were not adjusted for this type of error. Deaths at ages "not stated" were distributed proportionately within each age group, including subdivisions of the first year of life, for each race-sex population category. They represented less than one-tenth of 1 percent of total white deaths and less than three-tenths of 1 percent of total nonwhite deaths.

Calculation of  $q_x$ .—The formula for  $tq_x^{1949-51}$ , the probability of dying in the age interval  $x$  to  $x+t$  during the 3-year period, 1949-51, is usually taken as:

$$tq_x^{1949-51} = \frac{D_x^{1949-51}}{E_x^{1949-51} + t f_x^{1949} p_x^{1949} - t f_x^{1952} p_x^{1952}}$$

The numerator  $D_x^{1949-51}$  denotes the number dying in the 3-year period 1949-51, whose age at time of death is  $x$  to  $x+t$ . The denominator represents the number of exposures to the risk of death in the age interval  $x$  to  $x+t$  during the 3-year period 1949-51. The symbol  $E_x^{1949-51}$  denotes the number reaching exact age  $x$  during the 3-year period. The symbol  $t f_x^z$  denotes the fraction of the period between ages  $x$  and  $x+t$  that the  $p_x^z$  infants alive at ages  $x$  to  $x+t$  on January 1 of calendar year  $z$  are exposed, on the average, to the risk of death in calendar year  $z$ .

The method that was adopted for estimating the number of exposures involved two basic assumptions which simplified the computations considerably. For each race-sex group, it was assumed that:

- (a) the number of deaths among live births that would otherwise have attained age  $x$  during the 3-year period 1949-51, is the same as the observed number of deaths at ages prior to  $x$  that actually occurred during 1949-51 for each subdivision of the first year of life.
- (b) the number of births are divided equally among the days and distributed evenly over each day within each month of the calendar years 1948 and 1951.

Based on these assumptions, the denominator of  $\hat{q}_x^{1949-51}$  (the estimate of  $tq_x^{1949-51}$ ) is one-half the number of births who were exposed during only part of the age interval  $x$  to  $x+t$  in the period 1949-51 or would have been so exposed if they had not died, plus all other births who attained age  $x$  in the period 1949-51 or would have done so had they not died, less the number of deaths prior to age  $x$  in the period 1949-51. Thus  $\hat{q}_x^{1949-51}$ , the

estimate of the probability of dying during the second day of life is:

$$\hat{t}_x^{1949-51} = \frac{\text{Deaths in the period "1-2 days," } 1949-51}{B_{1949-51} + \frac{3}{62} (B_{12}^{1948} - B_{12}^{1951}) - D_{1949-51} \text{ under 1 day}}$$

where  $B^{1949-51}$  and " $D^{1949-51}$  under 1 day," respectively, denote the number of births and the number of deaths under 1 day in the 3-year period 1949-51, and  $B_j^z$  denotes the number of births during the  $j^{\text{th}}$  month of calendar year  $z$ . The estimate of the probability of dying during the second week of life is:

$$\hat{t}_x^{1949-51} = \frac{\text{Deaths in the period "1-2 weeks," } 1949-51}{B_{1949-51} + \frac{21}{62} (B_{12}^{1948} - B_{12}^{1951}) - D_{1949-51} \text{ under 1 week}}$$

And the estimate of the probability of dying during the twelfth month of life is:

$$\hat{t}_x^{1949-51} = \frac{\text{Deaths in the period "11-12 months," } 1949-51}{B_{1948-50} + \frac{1}{2} (B_1^{1951} - B_1^{1948}) - D_{1949-51} \text{ under 11 months}}$$

The estimates of the probability of dying for other subdivisions of the first year of life were obtained by analogous formulas. The formulas employed in the computation of the denominators are listed in table D. It will be noted that the portions of births included for calendar years 1948 and 1951 were not computed precisely for every age interval. Thus, the age interval "4 weeks-2 months" was treated as equivalent to "1 to 2 months," and differences in the length of calendar months were ignored. The computational refinements did not appear to be warranted in these infant life tables in view of their negligible effect. The denominators of the probabilities of dying for combinations of population groups were obtained by aggregating the denominators for the component population groups.

The original values of the probabilities of dying during subdivisions of the first year of life were adjusted slightly for nonwhite males, nonwhite females, total males, total females, and for the total population. This was done in order to achieve agreement between the infant mortality rates based

11-12 months-----	1/2 Jan. 1948 + Feb. 1948 through Dec. 1950 + 1/2 Jan. 1951	0-11 months in 1949-51

<sup>1</sup>The probability of dying during the interval "0-1 week" was derived directly from life table deaths during the first 7 days of life.

<sup>2</sup>The probability of dying during the interval "0-4 weeks" was derived directly from life table deaths during the first 4 weeks of life.

on them and on those calculated by another procedure and published in an earlier life table report.<sup>3</sup> In almost all instances in this report the published values of the probabilities of dying during subdivisions of the first year of life were unaffected by the adjustment. The adjustment method, itself, is described in the following section.

**Calculation of  $l_x$  and  $t^d_x$ .**—The values of  $l_x$  and  $t^d_x$  were obtained by successive multiplication starting with a radix of 100,000 live births by the formulas:

$$t^d_x = l_x \cdot t^q_x$$

$$l_{x+t} = l_x - t^d_x$$

In the computations, values of  $t^q_x$  were carried to seven decimal places unrounded, and three decimals unrounded were retained in the  $l_x$  and  $d_x$  values. The set of values of  $t^q_x$  for a population group was revised if the sum of the original set of  $t^d_x$  values for all subdivisions of the first year of life, rounded to the nearest integer, was different from the respective number of infant deaths,  $d_o$ , published in the previous life table report.<sup>4</sup> The adjustment was made by multiplying each of the original  $t^d_x$  values by the ratio,  $d_o$  divided by the sum of the original  $t^d_x$ . Revised values of  $l_x$  and  $t^q_x$  were obtained by reapplication of the above formulas.

The probabilities of dying during the intervals "0-1 week" and "0-1 month" were obtained by dividing the sum of the calculated deaths for subdivisions of the respective age intervals by the radix of 100,000 births. For example, the probability of dying during the interval "0-1 week" was computed as the sum of the calculated number of life table deaths on each day of the first week of life divided by the radix of 100,000 births.

In the published tables, all the  $l_x$  values were rounded to the nearest integer, while the  $d_x$  values were obtained by differencing the published  $l_x$  column, and, for that reason, differ slightly in some cases from the figures which would result from rounding the originally calculated  $d_x$  values directly. The published  $t^q_x$  values were rounded at five decimal places.

**Calculation of  $t^L_x$ .**—Except for the first day of life, it was assumed that infants who die between the age  $x$  and  $x + t$  live on the average half the period. The following formula was employed:

$$t^L_x = \frac{1}{2} t (l_x + l_{x+t})$$

The values of  $t$  were taken as 1/365, 7/365, and 28/365, respectively, for periods of 1 day, of 1 week, and of 28 days. The method employed to evaluate

$t$  as fractions of a year for longer periods was consistent with the processing rules used in the National Office of Vital Statistics in the regular tabulations of deaths by age. The first month of life was regarded as containing exactly 30 days and each successive month as containing exactly one-eleventh of the remaining 365 days or 30 and 5/11 days. Therefore, the period "28 days-2 months" contained 2 more than 30 and 5/11 days and the value of  $t$  was taken as 32 and 5/11 days divided by 365 days or 357/4015. The value of  $t$  for periods of exactly 1 month was taken as 30 and 5/11 days divided by 365 days or 335/4015.

For the first day of life,  $t^L_o$  was obtained by the formula:

$$t^L_o = t [l_o - (1 - t f_o) \cdot t^d_o]$$

where  $t f_o$  denotes the fraction of deaths under 1 day which occurred on the day following birth. Deaths under 1 day are not tabulated according to whether death occurred on the same day as birth or on the following day. Another alternative is to estimate the values of  $t f_o$  by making use of tabulations of deaths by subdivisions of the first day of life. However, detailed tabulations of that kind were not made during the 3-year period 1949-51, but it was felt that they could be approximated with sufficient accuracy from existing tabulations for purposes of evaluating  $t f_o$ . Of the total number of deaths under 1 day, the estimate of the proportion of deaths under 1 hour was based on a study of neonatal mortality conducted in connection with the 1950 test for the underregistration of births,<sup>5</sup> and the estimates of the proportion of deaths in each of the other subdivisions of the first day of life except for the interval "1-3 hours" were based on unpublished provisional tabulations of infant deaths for 1948. The undistributed proportion of deaths under 1 day was allotted to the interval "1-3 hours." The estimates of deaths under 1 day by age, race, and sex based on these computations are presented in table E.

It was assumed that within each age interval shown, 1/24 of the total deaths occurred on each hour of the first day of life, and that infants who died in each period lived on the average half the period. On this basis, only births during the last 1/2 hour of the first day of life, died under 1 hour of age on the second day of life. Therefore, 1/2 of 1/24, or 1/48 of the deaths under 1 hour, occurred on the day following birth. It may be helpful to give one further illustration. Only births during

<sup>3</sup>Op. cit., vol. 41, No. 1.  
<sup>4</sup>Op. cit., vol. 41, No. 1.  
<sup>5</sup>The tabulation is based on neonatal deaths among infants born in the United States between January 1 and March 31, 1950. For a discussion of the source of data, see "Weight at Birth and Its Effect on Survival of the Newborn in the United States, Early 1950," by Sam Shapiro and Jeanne Unger. Vital Statistics—Special Reports, vol. 39, No. 1, 1954.

TABLE E. ESTIMATES OF DEATHS UNDER 1 DAY BY AGE, RACE, AND SEX: UNITED STATES, 1949-51

AGE INTERVAL	WHITE		NONWHITE	
	Male	Female	Male	Female
Total under 1 day-----	53,129	37,948	10,828	8,212
Under 1 hour-----	10,412	8,789	2,120	1,684
1-3 hours-----	9,827	6,461	2,240	1,654
3-6 hours-----	9,932	6,282	2,160	1,463
6-12 hours-----	13,226	9,200	2,550	2,123
12-18 hours-----	6,725	4,936	1,233	926
18-24 hours-----	3,007	2,280	525	362

the last  $4\frac{1}{2}$  hours of the first day of life died in the age period "3-6 hours" on the second day of life. Therefore,  $9/2$  of  $1/24$ , or  $3/16$  of the deaths between 3 and 6 hours, occurred on the day following birth. Fractions for other subdivisions of the first day of life were obtained by similar reasoning and are distributed in table F.

The following procedure was employed to estimate the values of  $t f_o$  shown in table G for each race-sex category. The product of the number of deaths (shown in table E) and the proportion of deaths assumed to represent births of the previous day for the respective age period (shown in table F) gave the number of deaths during the particular age period representing births of the previous day. In a similar manner, the number of deaths representing births of the preceding day was obtained separately for each age interval, and the sum of these deaths was divided

TABLE F. PROPORTION OF DEATHS UNDER 1 DAY OF AGE ASSUMED TO REPRESENT BIRTHS OF THE PREVIOUS DAY

AGE AT DEATH	Assumed proportion born on previous day
Under 1 hour-----	1/48
1-3 hours-----	1/12
3-6 hours-----	3/16
6-12 hours-----	3/8
12-18 hours-----	5/8
18-24 hours-----	7/8

TABLE G. VALUES OF  $t f_o$  FOR DEATHS UNDER 1 DAY BY RACE AND SEX: UNITED STATES, 1949-51

RACE AND SEX	Values of $t f_o$
White males-----	0.276
White females-----	.275
Nonwhite males-----	.261
Nonwhite females-----	.260

by the total number of deaths under 1 day to obtain estimates of  $t f_o$  for each population category.

The values of  $t f_o$  are primarily of theoretical interest in this report since substantial variations in their values have very small effect on the resulting values of  $t L_x$  for the first day of life. For example, the published values of  $t L_x$  for the first day of life based on values of  $t f_o$  shown in table G and on values of  $t f_o$  equal to  $\frac{1}{2}$  would differ from each other by 1 at most in each of the 1949-51 life tables.

All values of  $t L_x$  were retained to two decimal places unrounded for use in subsequent calculations. The published  $t L_x$  values were obtained by differencing the published  $T_x$  column, and therefore differ slightly in some cases from the figures which would result from rounding the originally calculated  $L_x$  values directly.

Computation of  $T_x$  and  $\overset{o}{e}_x$ .—Values of  $T_x$  for subdivisions of the first year of life were obtained by adding the value of  $T_x$  at age 1, which was published earlier,<sup>6</sup> to the accumulated values of  $t L_x$  down to and including the youngest age interval. The values of  $\overset{o}{e}_x$  were computed by the formula:

$$\overset{o}{e}_x = \frac{T_x}{l_x}$$

The  $T_x$  values were unrounded at two decimals, and the  $l_x$  values were used to the full number of decimals originally retained. The published values of  $T_x$  were rounded to the nearest integer, and those of  $\overset{o}{e}_x$  were rounded at two decimals.

Values of  $T_o$  for the separate population groups published in this report are not precisely equal to the respective values of  $T_o$  published earlier. However, the differences are sufficiently small in all cases so that the published values of  $\overset{o}{e}_o$  in both reports are identical.

<sup>6</sup>Op. cit., vol. 41, No. 1.

### EXPLANATION OF THE COLUMNS OF THE LIFE TABLE FOR THE FIRST YEAR OF LIFE

Both the descriptive titles and the conventional actuarial symbols appear at the head of the columns in each of the tables. The description which follows gives a more detailed explanation of the seven columns of the life table.

*Column 1—Age interval ( $x$  to  $x+t$ ).*—The age interval shown in column 1 is the interval between the two exact ages indicated. For instance, "3-4 days" indicates the 24 hour interval between the completion of the third and fourth days following birth, in other words, the fourth day of life.

*Column 2—Proportion dying ( $tq_x$ ).*—This column shows the proportion dying in the indicated age interval during the first year of life among those alive at the beginning of the interval. For example, the proportion dying in the age interval "3-4 days" for white males is .00127. In other words, during 1949-51 out of every 100,000 white males alive at exactly 3 days of age, 127 would die before reaching 4 days of age. The "proportion dying" column forms the basis of the life table, all other columns being derived from it.

*Column 3—Number living ( $l_x$ ).*—This column shows the number of persons who survive to the beginning of the indicated age interval out of a cohort of 100,000 births, among whom the proportions dying in each age interval during the first year of life are exactly those shown in column 2. Thus, out of 100,000 white male babies born alive, 98,899 will complete the first day of life and enter the second, 98,549 will begin the third day; 98,033 will reach 1 week of age; and 96,960 will live to be 11 months old.

*Column 4—Number dying ( $td_x$ ).*—This column shows the number dying in each successive age interval during the first year of life out of 100,000 births. Out of 100,000 white males born alive, 1,101 will die in the first day of life, 350 on the second day, 136 in the second week of life, and 29 in the twelfth month of life. Each figure in column 4 is the difference between two successive figures in column 3.

*Columns 5 and 6—Stationary population ( $L_x$  and  $T_x$ ).*—Suppose that a group of 100,000 individuals like that assumed in columns 3 and 4 is born every year, and that the proportions dying in each such group in each age interval of the first year of life are exactly those shown in column 2 in this report and the proportions dying in each such group in each subsequent year of life throughout the lives of the members are exactly those shown in column 2 of United States Life Tables, 1949-51.<sup>7</sup> If there were no migration and if the births were evenly distributed over the calendar year, the survivors of these births would make up what is called a stationary population—stationary because in such a population the number of persons living in any given age interval would never change. When an individual left an interval, either by death or by growing older and entering the next higher age interval, his place would immediately be taken by some one entering from the next lower age interval. Thus, a census taken

at any time in such a stationary community would always show the same total population and the same numerical distribution of that population among the various age intervals. In such a stationary population supported by 100,000 annual births, column 3 shows the number of persons who, each year, reach the beginning of the age interval indicated in column 1, while column 4 shows the number of persons who die each year in the indicated age interval.

Column 5,  $L_x$ , shows the number of persons in the stationary population in the indicated age interval of the first year of life. For example, the figure given for white males in the age interval "3-4 days" is 269. This means that a stationary population supported by 100,000 annual births and with proportions dying in each age group interval always in accordance with column 2, a census taken on any date would show 269 infants between 3 and 4 days old. The number of persons in the stationary population in each year of life at subsequent single years of age, is shown in column 5 of United States Life Tables, 1949-51.<sup>8</sup>

Column 6,  $T_x$ , shows the total number of persons in the stationary population (column 5) in the indicated age interval and all subsequent age intervals. For example, in the stationary population of white males referred to in the last illustration, column 6 shows that there would be at any given moment a total of 6,630,565 persons who are 3 days old or older. The population at all ages 0 and above (in other words, the total population of the stationary community) would be 6,631,377.

*Column 7—Average remaining lifetime ( $e_x$ ).*—The average remaining lifetime (also called the complete expectation of life) at any age is the average number of years to be lived by those surviving to that age, on the basis of a given set of age-specific rates of dying. In order to arrive at this value, it is first necessary to observe that the figures in column 5 of the life tables can also be interpreted in terms of a single life table cohort, without introducing the concept of the stationary population. From this point of view, each figure in column 5 represents the total time (in years) lived between the beginning and end of the indicated age interval by all those reaching the beginning of the age interval among the survivors of a cohort of 100,000 live births. Then, the figure 269 for white males in the age interval "3-4 days" is the total number of years lived during the fourth day of life by the 98,310 (column 3) who reach the age of exactly 3 days out of 100,000 infants born alive. The corresponding figure in column 6 (6,630,565) is the total number of years lived after attaining 3 days of age by the 98,310 reaching that age. This number of years divided by the number of persons (6,630,565 divided by 98,310) gives 67.45 years as the average remaining lifetime of white males at age 3 days.

## Life Tables for the Geographic Divisions of the United States: 1949-51

This report contains the detailed 1949-51 life tables for the nine geographic divisions of the United States. Separate life tables are presented for males and females among the white population and among the nonwhite population for each division. Detailed life tables by race and sex were computed for the four regions but are not being published. These unpublished life tables are available upon request.

The mortality rates form the basis of the life tables. In general, the mortality rates in this report are based on the 1950 Census of Population and on the average annual number of resident deaths during the 3-year period 1949-51. In deriving the mortality rates at ages under 5, use was made of reported births for each of the 8 years 1944 to 1951, and of deaths among them during this period. Special methods were devised to estimate the mortality rates at ages over 87 for nonwhites, and at ages over 92 for whites because the recorded population and death figures at these ages were regarded as unreliable. Therefore, the life table values at the old-

est ages may not represent actual conditions.

The life table assumes that a hypothetical cohort traced from birth is subject, through successive ages, to the mortality rates of a population group under observation during a specified period. For example, table 1 presents a life table for white males in New England; this shows the experience of a cohort starting with 100,000 live births and subject to the average annual mortality rates for successive ages during the 3-year period 1949-51.

The life table shows for this hypothetical cohort the average number of remaining years of life among those who reach each age. The text table below presents values of the average remaining lifetime at selected ages for the United States and its geographic divisions according to the 1949-51 life tables. Values are shown at birth and at ages 25 and 65 for white and nonwhite males and females.

These life tables were computed in the Statistical Bureau of the Metropolitan Life Insurance Company.

Source: Divisional life tables were computed in the Statistical Bureau of the Metropolitan Life Insurance Company from mortality data supplied by the National Office of Vital Statistics and population data supplied by the U. S. Bureau of the Census.

## EXPLANATION OF THE COLUMNS OF THE LIFE TABLE

(Values shown are from table 1)

*Column 1—Year of age ( $x$  to  $x + 1$ ).*—The year of age, shown in column 1, is the interval between the two exact ages indicated. For instance, "21-22" indicates the interval between the twenty-first birthday and the twenty-second, in other words, the twenty-second year of life.

*Column 2—Proportion dying ( $q_x$ ).*—This column shows the proportion dying within 1 year after the birthday indicated among those alive on that birthday. For example, the proportion dying in the age interval 21-22 for white males is .00122. In other words, during 1949-51, out of every 1,000 white males alive and exactly 21 years old, 1.22 would die before reaching their twenty-second birthday. The "proportion dying" column forms the basis of the life table, all the other columns being derived from it.

*Column 3—Number living ( $l_x$ ).*—This column shows the number of persons who survive to each age out of a cohort of 100,000 live births, among whom the proportions dying in each age throughout their lives are exactly those shown in column 2. Thus, out of 100,000 white male babies born alive, 97,291 will complete the first year of life and enter the second; 97,129 will begin the third year; 95,708 will reach age 21; and 37,409 will live to age 75.

*Column 4—Number dying ( $d_x$ ).*—This column shows the number dying in each successive year of age out of 100,000 live births. Out of 100,000 white males born alive, 2,709 die in the first year of life, 162 in the second year, 117 in the twenty-second year, and 2,854 in the seventy-sixth year. Each figure in column 4 is the difference between two successive figures in column 3.

*Columns 5 and 6—Stationary population ( $L_x$  and  $T_x$ ).*—Suppose that a group of 100,000 individuals like that assumed in columns 3 and 4 is born every year, and that the proportions dying in each such group in each year of life throughout the lives of the members are exactly those shown in column 2. If there were no migration and if the births were evenly distributed over the calendar year, the survivors of these births would make up what is called a stationary population—stationary because in such a population the number of persons living in any given year of age would never change. When an individual left an age, either by death or by growing older and entering the next higher age, his place would immediately be taken by some one entering from the next lower age. Thus, a census taken at any time in such a stationary community would always show the same total population and the same numerical distribution of that population among the

various ages. In such a stationary population supported by 100,000 annual births, column 3 shows the number of persons who, each year, reach the birthday indicated in column 1, while column 4 shows the number of persons who die each year in the indicated age interval.

Column 5,  $L_x$ , shows the number of persons in the stationary population in the indicated age interval. For example, the figure given for white males in the year of life 21-22 is 95,649. This means that in a stationary population of white males supported by 100,000 annual births and with proportions dying in each age group always in accordance with column 2, a census taken on any date would show 95,649 persons between 21 and 22 years old.

Column 6,  $T_x$ , shows the total number of persons in the stationary population (column 5) in the indicated age interval and all subsequent age intervals. For example, in the stationary population of white males referred to in the last illustration, column 6 shows that there would be at any given moment a total of 4,658,765 persons who have passed their twenty-first birthday. The population at all ages 0 and above (in other words, the white male population of the stationary community) would be 6,686,047.

*Column 7—Average remaining lifetime ( $\bar{e}_x$ ).*—The average remaining lifetime (also called the complete expectation of life) at any age is the average number of years remaining to be lived by those surviving to that age, on the basis of a given set of age-specific rates of dying. In order to arrive at this value, it is first necessary to observe that the figures in column 5 of the life tables can also be interpreted in terms of a single life table cohort, without introducing the concept of the stationary population. From this point of view, each figure in column 5 represents the total time (in years) lived between the two indicated birthdays by all those reaching the earlier birthday among the survivors of a cohort of 100,000 live births. Thus, the figure 95,649 for white males in the year of life 21-22 is the total number of years lived between the twenty-first and twenty-second birthdays by the 95,708 (column 3) who reach the twenty-first birthday out of 100,000 white males born alive. The corresponding figure in column 6 (4,658,765) is the total number of years lived after attaining age 21 by the 95,708 reaching that age. This number of years divided by the number of persons (4,658,765) gives 48.68 years as the average remaining lifetime of white males at age 21.

TABLE 1. LIFE TABLE FOR WHITE MALES: NEW ENGLAND DIVISION, 1949-51

YEAR OF AGE	PROPORTION DYING	OF 100,000 BORN ALIVE		STATIONARY POPULATION		AVERAGE REMAINING LIFETIME

# **Method of Constructing the 1949-51 National, Divisional, and State Life Tables**

**U. S. DEPARTMENT OF HEALTH, EDUCATION, AND WELFARE**  
**Public Health Service**                           **National Office of Vital Statistics**

## PREFACE

This report describes the methods of constructing the decennial national (1), divisional (2), and State life tables (3) for 1949-51. Beginning with the census of 1900, national life tables have been prepared decennially and have appeared in Federal Government publications. These tables are based on the population data collected in the census and on mortality statistics referring to a 2- or 3-year period straddling the census date. Life tables for selected States were prepared in conjunction with national life tables for 1900-02 (4), 1909-11 (5), and 1919-20 (6). Life tables for each State, except Texas, were prepared for 1929-31 (7) and for all States and geographic divisions for 1939-41 (8, 9).

After experimenting, it was decided to construct the 1949-51 decennial life tables by following very closely the methods used by Dr. T. N. E. Greville (10) in preparing the 1939-41 national life tables. The problems of adjusting the recorded population and vital statistics and the graduation of these data for the 1949-51 life tables were

similar to those encountered in constructing the 1939-41 life tables because the national vital statistics system and population census methods for the United States were already well developed by 1940. By adopting similar methods for constructing life tables, differences between the tables for 1949-51 and for 1939-41 introduced by variations in computation procedure are minimized.

Part I of this report describes the construction of the national, divisional, and State life tables for 1949-51. Part II is a reproduction of pages 101-136 of the *United States Life Tables and Actuarial Tables, 1939-41* by Thomas N. E. Greville (National Office of Vital Statistics, 1947) which is out of print. This is the part of Greville's report containing the description of the methods of construction used by him for the life tables.

Acknowledgement is made to Dr. T. N. E. Greville who was consulted at all stages in the preparation of the national and subnational life tables, and to Mr. G. A. Carlson for his assistance in the computation of the national life tables.

## **Method of Constructing the 1949-51 National, Divisional, and State Life Tables**

By Monroe G. Sirken, Ph.D., Chief, Actuarial Analysis and Survey Methods Section, National Office of Vital Statistics, and Mortimer Spiegelman, Associate Statistician, Metropolitan Life Insurance Company

### **PART I**

#### Introduction

The experimental work and the construction of the national life tables were conducted in the National Office of Vital Statistics. In this section, reference will be made to part II of this report, "Method of Construction and Graduation of the 1939-41 Life Tables," when the methodology used for the 1939-41 life tables is applicable to the construction of the 1949-51 life tables. However, departures from the methods described there will be explained in some detail.

In deciding on the methods to use in constructing the national life tables, consideration was given to their utility in constructing the subnational tables. Hence it is not accidental that essentially the same methods were used in constructing the divisional and State life tables for 1949-51 in the Statistical Bureau of the Metropolitan Life Insurance Company. Deviations from the national tables in constructing the subnational tables are indicated. It is noteworthy that all computations for the subnational life tables were performed by machine methods. Conventional IBM equipment was used in all steps through calculation of the mortality rates and a Univac electronic computer was used for calculating the values of the other life table functions.

National life tables, nine in number, were constructed for total persons and for each sex, and corresponding sets for white persons and for nonwhite persons. Life tables were also computed separately for white and nonwhite persons of each sex in each of the nine geographic divisions. For the white population, life tables were computed separately for males and females in each State and the District of Columbia, and for the nonwhite

population life tables were computed separately for males and females in each State of the South Atlantic, East South Central, and West South Central Divisions.

The population data enumerated as of April 1 used in the construction of the national and sub-national life tables were published by the U. S. Bureau of the Census in *U. S. Census of Population: 1950, Volume II, Characteristics of the Population, Part 2, Chapter B, Table 15; and Chapter C, table 51* (1953).

Birth and death data were extracted from the following annual issues of *Vital Statistics of the United States* published by the National Office of Vital Statistics:

- 1944 Part II, table 3.
- 1945 Part II, tables 3 and 19.
- 1946 Part II, tables 4 and 20.
- 1947 Part II, tables 3 and 21.
- 1948 Part II, tables 5 and 21.
- 1949 Part II, tables 3 and 22.
- 1950 Volume II, table 17; and Volume III, table 56.
- 1951 Volume I, table 21; and Volume II, table 57.

#### Preliminary Adjustment of the Data

*Birth and death data.*--The few deaths of unknown age were prorated over the known ages.

It was assumed that the registration of births and deaths under 5 years of age were equally complete, so that adjustment in the recorded data was not necessary for the computation of mortality rates at these ages. This is a departure from Greville, who assumed that registration of births and deaths under 1 year of age were equally com-

plete, but less complete than registration of deaths at ages 1 through 4 years. The new assumption was made in consideration of the substantial improvement in the level of birth registration completeness between 1940 and 1950.

*Population data.*—Experimental national life tables for white females, based upon an estimated population for July 1, 1950, showed very little difference from corresponding tables based upon the census of population as of April 1. An adjustment of the census population figures to July 1 depends upon a number of assumptions, and in addition, would have been costly and difficult to make for use in the computation of the subnational life tables. Accordingly, the national, divisional, and State life tables for 1949-51 were based on the population enumerated in the census as of April 1, 1950, rather than as of July 1, the midpoint of the 3-year period for which deaths are used.

By 1951 there was a sizable United States population abroad. Trial computations indicated that the incorporation of the experience of the population outside of the United States would have virtually no effect on the results and consequently no adjustment was made for them.

The complete count data in the reports from the 1950 census of population were by 5-year-age groups up to age 75 years, the residual age groups being for 75-84 years and for 85 years and over. The population counts at ages 75 years and over were distributed into 5-year-age groups, with a residual class for ages 100 years and over, on the basis of the 20-percent sample count by single years of age.

*Special adjustment of nonwhite data.*—The statement of age reporting on the death certificates and on the population enumerations around age 65 years was investigated for both the white and non-white population. In the case of the white population, the apparent misstatement of age was not considered sufficient to seriously affect the life table values; unadjusted data were therefore used. In the case of the nonwhite, when misstatement of age was sufficiently marked to affect the life table values, the method used by Greville to redistribute recorded deaths and the population around age 65 years was followed. Adjustments were made for ages 50 through 70 years, whereas Greville made his adjustments for ages 55 to 70 years, in 1940.

The procedure used in this study to redistribute the nonwhite population and deaths at ages 50-69 years follows:

If

$$W_x = \text{White population (or deaths) at ages } x \text{ and over}$$

$$N_x = \text{Nonwhite population (or deaths) at ages } x \text{ and over}$$

$$r_x = N_x \div W_x$$

And given

$$r_{45}, r_{50}, r_{70}, r_{75}$$

Then by Waring's formula

$$r'_{55} = -.4r_{45} + 1.2r_{50} + .4r_{70} - .2r_{75}$$

$$r'_{60} = -.4r_{45} + .9r_{50} + .9r_{70} - .4r_{75}$$

$$r'_{65} = -.2r_{45} + .4r_{50} + 1.2r_{70} - .4r_{75}$$

For  $x = 55, 60, \text{ and } 65$

$$N'_x = r'_x \cdot W_x$$

The redistributed nonwhite population (or deaths) in 5-year-age groups,  $5N'_x$ , is then

$$5N'_{50} = N_{50} - N'_{55} \quad 5N'_{60} = N'_{60} - N'_{65}$$

$$5N'_{55} = N'_{55} - N'_{60} \quad 5N'_{65} = N'_{65} - N_{70}$$

#### Computation of Mortality Rates

Table 1 digests the procedure used in this phase of the construction of the life tables.

*Ages 0-4 years.*—The procedures used by Greville to compute mortality rates by single years of age under 5 years were duplicated for the most part in the construction of the 1949-51 life tables. The separation factors for the first year of life used in the construction of the 1949-51 life tables are shown in table 2. Since a moderate variation in the separation factor at ages 1-4 years

1951-----	.1149	.1300	.1697	.1741

has only a slight effect on the mortality rates the separation factors at these ages were assumed to be one-half (11). Trial calculations indicated that no adjustment was needed at ages 0-4 years for migration in the construction of the national and subnational life tables; also, as indicated previously with regard to these data, no adjustment was needed in the life tables for the years 1949-51 to correct for differentials in completeness of registration of births and deaths under 5 years of age. Whenever necessary, adjustments were made in the mortality rates under 5 years as computed from basic data in the subnational tables to remove anomalies, the principal ones being rates that advance with age and

rates for females higher than for males in the same area.

*Ages 5 years and over.*—The formulae used for the computation of population and deaths at the pivotal ages from age 7 years to the very old ages are indicated in table 1. The highest pivotal ages based upon census population and NOVS death data were 92 years for the white population and 87 years for the nonwhite; the use of pivotal age data at the higher ages would have introduced irregularities in the mortality curve. Table 1 also refers to the formula used to compute mortality rates at the pivotal ages.

To obtain mortality rates at the higher pivotal ages an extrapolation was made by Greville's method, and the results were compared with those produced by using one set of mortality rates at the highest ages based upon data by Vincent (12) and another set based on Civil War data by Myers and Shudde (13). The mortality rates from Vincent were incompatible with the acceptable rates at ages up to 92 years for the white population and up to 87 for the nonwhite, but this was not the case for the Civil War veteran data. The latter were accordingly used for pivotal mortality rates at the terminal ages of 102, 107, 112, and 117 years for each race and sex category. The mortality rates at the pivotal ages between the last accepted age and age 102 years were obtained by interpolation using Waring's formula. In the life tables combining both white and nonwhite, the pivotal mortality at age 92 years was computed in a special way. The pivotal

value of the number of deaths for the nonwhite population, as originally calculated, was regarded as correct but an adjusted population count for the nonwhite was obtained by dividing the number of deaths by the mortality rate at this age obtained by interpolation.

The mortality rates for the single year ages between the pivotal ages were computed according to the interpolation formulae indicated in table 1. As required, adjustments were made in the mortality rates at pivotal and interpolated ages in the subnational tables to remove anomalies or undulations in the mortality curve. The anomalies were generally isolated instances where the mortality rate for females was higher than for males, or the rate for the white population higher than for the nonwhite.

#### Calculation of Other Life Table Functions

To compute the  $L_0$  in each of the 1949-51 national life tables, the infant deaths in each of the 3 years were separated according to the calendar year of birth by means of the separation factor for each year, and the results were summed to compute a composite separation factor for the 3-year period. The same separation factors were used in each of the corresponding subnational life tables. The remaining life table functions were computed by conventional methods as described by Greville (part II, pages 195 and 194).

## PART II

### METHOD OF CONSTRUCTION AND GRADUATION OF THE 1939-41 LIFE TABLES

(Pages 163-198 of Part II are exact copies of pages 101-136  
of the *United States Life Tables and Actuarial Tables, 1939-41*, by Thomas N. E. Greville.)

## PART V

### METHOD OF CONSTRUCTION AND GRADUATION OF THE LIFE TABLES

The entire process of constructing a life table consists of three major steps: (1) the preliminary adjustment of the population, birth, and death statistics which are to be used, in order to remove any errors and biases for which corrections are available or can be derived; and the approximation of certain detailed distributions of the data, needed in the computations but not available from the actual tabulations; (2) the calculation, from the adjusted data, of the rates of mortality for each year of age, which form the basis of the life tables; and (3) the computation of the remaining life table values. Of these, the first step is by far the most difficult. While the second step requires technical skill and the exercise of judgment, valuable assistance is provided by the large body of literature on the subject and the accumulated experience of actuaries in the construction of life tables. The third step involves little more than the routine application of standard formulas. However, in making the preliminary adjustment of the data, it is necessary to break new ground, as comparatively little attention has been given to this subject, and, besides, the data of each country and each epoch present their own peculiar problems, so that past experience is not a satisfactory guide.

The following description of the methods and processes used is divided into three main sections corresponding to the three major steps in the construction of a life table.

#### A. PRELIMINARY ADJUSTMENT OF THE DATA

In this section, the description of the various preliminary adjustments made in the data of births, deaths, and populations has been arranged in approximately the order in which the various operations were actually carried out. This order was adopted in order to avoid complicating unnecessarily the explanation of many of the steps, but does not correspond to any systematic classification of the various adjustments by either the purpose of the adjustment or the class of data involved. The adjustments made are of four types: (1) those intended to correct for incompleteness of reporting, (2) those necessitated by incomplete or inaccurate age statements, (3) those intended to eliminate roughness due to the small volume of data in certain classifications, and (4) the estimation of certain figures needed in the construction of life tables but not available from actual tabulations. Adjustments of the first type were confined to statistics of births and infant deaths. In the

latter case, the adjustment of (a) the total infant deaths, and (b) the figures for subdivisions of the first year of life are separately discussed. The second type of adjustment includes the treatment of deaths for which age was not reported, and the redistribution of Negro populations and deaths at ages 55 to 69. The only adjustment of the third type was a redistribution by month of age of deaths at ages 1 month to 11 months of nonwhite infants other than Negroes. The principal adjustment of the fourth type is that made for the change in the distribution of population between April 1, 1940, the date of the census, and July 1, 1940, the date on which populations were needed for the purpose of life table construction. Also included in this category is the estimation of the distribution by single years of age of the foreign-born population under age 5, this being needed for a special purpose, as explained later.<sup>1</sup>

#### Accuracy of the data

It has been stated that the life tables in this volume are based on the results of the 1940 census of population and the tabulations of reported deaths in the continental United States for the 3 years 1939-1941. In deriving life table values for ages under 5, use was made also of the tabulations of reported births for the years 1934 to 1941, inclusive, and of deaths under 5 years of age during those years. If all these data were known to be absolutely complete and correct, the construction of life tables from them would present few problems. However, the data are affected by two main types of error: (a) incompleteness or under-reporting, and (b) misstatement of age in populations and deaths, which makes the figures too large at some ages and too small at others. As will be explained later, some adjustment has been made for errors of type (b) through the graduation of the data, and, in the case of the Negro data, by a preliminary redistribution of the numbers in certain age groups for which this type of error was believed to be especially marked. Except in the case of statistics of births and infant deaths (those occurring at ages under 1 year), no attempt has been made to adjust for errors of type (a).

If it should happen that the enumeration of the population and the reporting of deaths were both deficient by exactly the same percent, the use of the unadjusted figures would produce exactly the correct mortality rates. However, if the reporting of deaths should be more complete than the enumeration of

<sup>1</sup> See p. 119.

## UNITED STATES LIFE TABLES AND ACTUARIAL TABLES

population, the rates of mortality would be overstated by using the reported figures. If, on the contrary, the enumeration of population should be more complete than the registration of deaths, the mortality rates would be understated. Using the unadjusted data thus involves the assumption that the reporting of deaths and the enumeration of population have the same degree of completeness. It would be a remarkable coincidence if this were exactly true. It would be even more remarkable if it were true, not only in the aggregate but within each of the various subdivisions by sex, race, and age, for which rates of mortality have been calculated. This assumption has been made then, not because it is believed to be precisely correct, but because specific information regarding the relative completeness of death reporting and census enumeration is almost entirely lacking.

## Completeness of birth registration

It has long been recognized that the census enumeration of children under 5, and particularly of those under 1 year, is markedly deficient. This is illustrated by the following figures relating to the 1940 census. The total native population enumerated as under 1 year of age on April 1, 1940, the date of the census, is closely<sup>2</sup> estimated as 2,019,662. The same population estimated from registered births and deaths during the year ending April 1, 1940, is 2,192,557, which exceeds the census figure by 172,895. Since it is known that birth registration is not entirely complete, the deficiency in the census enumeration of children under 1 year of age is actually greater than that num-

<sup>1</sup> The only estimation involved is in determining the deduction for foreign-born nonwhites which are given only by 5-year age groups and only for the principal nonwhite races. By the most liberal estimate, the number of these is less than 100.

<sup>1</sup> Grove, Robert B., *Studies in Completeness of Birth Registration, Part I, Completeness of Birth Registration, United States, Dec. 1, 1939, to Mar. 31, 1940*, U. S. Bureau of the Census, Vital Statistics—Special Reports, vol. 17, No. 18, p. 228, 1943.

<sup>2</sup> The States of Idaho, Maine, Nevada, New Hampshire, Utah, Vermont, and Wyoming, each of which reported less than 500 nonwhite births in the period 1939–1941 are omitted.

## PRELIMINARY ADJUSTMENT OF DATA

103

ber. For this reason birth statistics were relied upon in obtaining a population base for the rate of mortality in the first year. This raises the question as to how completely births are reported.

Following the 1940 census, there became available for the first time reliable information as to the completeness of birth registration in the United States. This information was obtained by preparing special infant cards for all infants enumerated in the census who were under 4 months of age on April 1, 1940, and by matching these cards against copies of the birth certificates for all births reported as having occurred between December 1, 1939, and April 1, 1940. Copies of all death certificates of infants born in this 4-month period were also obtained, and matched where possible with the birth certificates. Table AB shows, for white and nonwhite separately, the number of births reported in each State in the 3-year period 1939-1941, the percent completeness of birth registration as indicated by the test just described, and the adjusted number of births obtained by dividing the number of registered births by the proportion of births registered. In the case of the nonwhite, those States in which less than 500 nonwhite births were reported in the 3-year period have been omitted from the table.

Further tabulations were made for a special sample of infant cards, which yield the completeness of birth registration by a more detailed racial classification for the United States as a whole. This sample did not include matching with death records; and, for this reason, the results obtained are probably somewhat more suitable for use in adjusting birth statistics to be employed in the construction of life tables, since those infants whose deaths are registered probably constitute a biased sample from the standpoint of birth registration. Table AC shows, for whites, Negroes, and other races separately, the number of births reported in the 3-year period in the continental United States, the percent completeness of registration as obtained from the tabulation of the sample, and the adjusted number of births obtained by dividing the registered figure by the indicated proportion of births registered.

TABLE AC.—REGISTERED AND ADJUSTED BIRTHS, 1939-1941, BY RACE, AND PERCENT COMPLETENESS OF BIRTH REGISTRATION (EXCLUDING MATCHED INFANT DEATH RECORDS), DEC. 1, 1939, TO MAR. 31, 1940: UNITED STATES

RACE	Registered births	Percent completeness, Dec. 1, 1939, to Mar. 31, 1940	Adjusted births
White.....	6,255,527	83.98	6,656,232
Negro.....	843,483	81.87	1,030,271
Other races.....	40,404	75.05	53,836

<sup>1</sup> Based on tabulation of special sample.

## Completeness of registration of infant deaths

It has already been mentioned that all death statistics were used without any adjustment for incompleteness of reporting, with the exception of infant deaths: that is, those occurring under 1 year of age. In the construction of all the life tables prepared by the Bureau of the Census prior to 1940, even infant deaths were not adjusted for underreporting. However, there is evidence that the proportion of infant deaths not reported is sufficiently large to have an appreciable effect on life table values, and it appears that the former practice of relating fully adjusted birth data to unadjusted infant death statistics has resulted in a substantial understatement of the rate of mortality at age 0.

The problem of making a proper adjustment for incomplete reporting of infant deaths is a difficult one, because almost no information is available bearing directly on the point, and an indirect method of approach must be resorted to. This approach is based on an examination of infant mortality rates for subdivisions of the first year of life. Table AD shows, for each State included in table AB, the number of deaths occurring in the 3-year period 1939-1941 in each of seven subdivisions of the first year of life, per 1,000 adjusted births (table AB) in the same period. With the exception of the column pertaining to deaths under 1 day of age, these figures cannot be regarded as mortality rates in the true sense of the word, as the denominator used was, in each case, the number of births for the year, and not the number of survivors to the beginning of the age period indicated. However, this refinement would have comparatively little effect on the comparison between States, which is the chief purpose in view.

For convenience in making comparisons, the various States appear in table AD in decreasing order of the completeness of birth registration. A careful study of the table shows that there is a close relationship between the completeness of birth registration and the actual level of infant mortality in the various States. For example, if the 48 States and the District of Columbia are ranked also according to the mortality rate among white infants 9 to 11 months of age, it is found that of the 10 States having the most complete registration, 5 are also among the 10 having the lowest mortality rates. Likewise, among the 10 having least complete registration, 4 are also among the 10 having the highest mortality rates. This is not surprising, because, generally speaking, those States having the most efficient registration are States in which sanitation and public health measures have made relatively greater progress.

<sup>1</sup> See footnote 2 to table AB, p. 102.

However, if the comparison is made with the mortality rates for infants under 1 day old, instead of those aged 9 to 11 months, just the opposite tendency is observed, the lower mortality rates being recorded, in general, in the States with less complete registration of births. For example, among the 10 States having the least complete registration of white births, 5 were also among the lowest 10 when ranked according to the mortality rate for white infants under 1 day old. It might be expected that mortality rates for infants in the first day of life would fail to show the close relationship to the completeness of birth registration which was observed in the case of the rates for infants 9 to 11 months old, because a large proportion of deaths occurring immediately after birth are due, at least in part, to mechanical causes connected with the process of childbirth. The great improvement in infant mortality in recent years has, in fact, affected the frequency of neonatal deaths to a much less degree than that of deaths occurring later in infancy.

It is not, however, to be expected that the death rate in very early infancy would be totally unaffected by varying conditions in the environment. Still less can it be thought that the normal relationship is actually reversed,<sup>3</sup> the lower mortality rates occurring where conditions are less favorable. It is necessary, therefore, to look for some source of error in the mortality rates for the first day of life as shown in table AD. Inasmuch as these rates were obtained from births corrected for incomplete registration, but without any corresponding adjustment in the death statistics, the most natural inference is that deaths occurring in early infancy are affected by an incompleteness of reporting having, in general, the same geographical incidence as in the case of births.

The relationships which led to this conclusion are brought out more clearly in table AE, which shows the results of arranging the States in the order of the percent completeness of birth registration and then combining them into five groups (three groups in the case of nonwhites) in such a way that the total number of reported deaths under 1 year of age is approximately the same for each group used. In the case of the data for white lives, the States of Arizona, New Mexico, and Texas have been omitted, because in these States the mortality rates for white infants in the latter part of the first year of life are so much higher than those for other States that the general relationship would be obscured by their inclusion. This condition is believed to be due to the presence, in the white population of these States, of a large number of Mexican agricultural workers in low income groups, among whom the rate of infant mortality is extremely high. Except for the omission of these 3 States from group 4, the spacing in table AD indicates the particular States included in

<sup>3</sup> There are certain factors tending to cause fewer deaths in the first day of life when the general infant death rate is high. For example, there are probably fewer instrumental deliveries in areas of high mortality. However, the effect of such factors is believed to be small.

## PRELIMINARY ADJUSTMENT OF DATA

105

each group. In making the calculations for nonwhites, the 7 States having less than 500 nonwhite births in the 3-year period, which were omitted from tables AB and AD, were again omitted here. Upon examining the part of table AE which shows data for the white population, it is observed that the percent completeness of birth registration decreases rather slowly in the first three groups and then falls at an accelerating pace as groups 4 and 5 are reached. The States in group 5 (where registration is least complete) contain only 18 percent of the adjusted white births in all five groups but contain 45 percent of the assumed unregistered (adjusted less registered) births. Above the age of 1 week, the death rates based on adjusted births rise consistently from group 1 to group 5, but in the case of deaths in the first day of life, the rates begin to decrease with group 4, and group 5 actually shows the lowest death rate of the five groups. In the age period 1 day to 1 week, a less marked but similar tendency is observed. The behavior of the rates for these two youngest age periods strongly suggests that the decline which appears in groups 4 and 5 may be spurious, and attributable, as already intimated, to incomplete reporting of deaths occurring in early infancy in these States. Among the nonwhite, the tendency toward lower apparent death rates in those States having less complete registration of births is more marked, and persists throughout the entire first year of life.

TABLE AE.—DEATHS UNDER 1 YEAR PER 1,000 ADJUSTED BIRTHS, BY AGE AND RACE, 1939-1941, FOR GROUPS OF STATES ARRANGED ACCORDING TO THE COMPLETENESS OF BIRTH REGISTRATION

	WHITE <sup>1</sup>					NONWHITE <sup>2</sup>		
	State group <sup>3</sup>					State group <sup>3</sup>		
	1	2	3	4	5	1	2	3
Percent of total deaths under 1 year for all groups	18.1	19.6	18.4	22.8	21.1	31.3	36.4	32.3
Percent completeness of birth registration	99.0	97.7	96.8	92.8	85.0	92.7	83.3	71.0
Deaths per 1,000 adjusted births:								
Under 1 day	12.6	12.7	12.9	12.8	11.8	15.8	13.3	10.6
1 day to 1 week	7.9	7.8	8.4	8.4	8.2	12.4	10.6	10.4
1 week to 1 month	3.7	3.9	4.2	5.0	5.2	7.8	8.6	7.8
1 and 2 months	4.0	4.4	4.9	5.5	6.0	9.2	9.7	8.7
3 to 5 months	3.3	3.9	4.4	4.9	5.2	9.3	9.4	8.9
6 to 8 months	2.0	2.4	2.5	3.0	3.3	6.4	6.0	5.8
9 to 11 months	1.3	1.6	1.7	2.1	2.4	4.2	3.9	3.9

<sup>1</sup> The States of Arizona, New Mexico, and Texas were omitted from the computations for white lives. See text, p. 104.

<sup>2</sup> Those States reporting less than 500 births of nonwhites in 1939-1941 were omitted from the computations. See footnote to table AB, p. 102.

<sup>3</sup> Higher numbers indicate less complete registration, as shown in the second line of the table.

In summary, it may be stated that the preceding analysis appears to show: (1) that there is substantial underreporting of infant deaths, (2) that this underreporting tends, in general, to be greater in those States in which underreporting of births is greater, and (3) that it is relatively greater in the case of deaths occurring in the first week of life than for those which occur later. However, it is not sufficient, for the purpose of life table construction merely to know that such

a condition exists. It is necessary also to make some assumption as to the magnitude of the underreporting. As no information was available from which this could be estimated directly, an effort was made to estimate it indirectly by assuming the percent of nonreporting of infant deaths to be some fixed proportion or multiple, State by State, of the percent of nonreporting of births and adjusting the State death rates in accordance with that assumption, and then examining the death rates based on various assumed proportions or multiples to see which produced results most nearly in accordance with expectation. It was considered that, when adequately adjusted, the State death rates in each age period should show a consistent tendency to increase with decreasing completeness of birth registration, since, in general, the States having more complete registration are also those with better sanitation and public health facilities.

Such calculations were made for the first three age periods employed in table AD, which together comprise the first month of life. Since the individual State figures show minor fluctuations which make it difficult to observe the general tendency, these calculations were made for the same groups of States which were used in table AE. Three different sets of calculations were made, based on the assumption that the percent adjustment required for incomplete reporting of deaths in each age period was (a) 50 percent, (b) 100 percent, and (c) 150 percent of the corresponding percent adjustment required for births in the same State. The results of the calculations are shown in table AF.

In the case of white infant deaths under 1 day, adjustment in accordance with assumption (a) still leaves group 5 with a lower death rate than group 4. Assumption (b) produces a death rate in group 5 which is slightly higher than that in group 4, but the difference is much less than might reasonably be expected in view of the substantial difference in the completeness of birth registration in the two groups. In the case of the nonwhite, even assumption (c) fails to produce increasing death rates, although it tends in that direction, indicating that a more drastic adjustment would do so. The implication of these observations that deaths occurring in the first day of life may be less completely registered than births is less startling than it may at first appear, if one considers that there is probably a substantial number of cases of very early death, especially in rural areas and among the more underprivileged classes, in which neither the birth nor the death is registered. This group would of course constitute a much larger percent of the total infant deaths than of the total births. It is also possible that there may be a tendency, in some States, to report such cases as stillbirths.

In the case of white deaths at ages 1 day to 1 week, assumption (a) gives death rates which increase, but not by a sufficient amount, while the rates resulting from assumption (b) appear reasonable. For the non-

## UNITED STATES LIFE TABLES AND ACTUARIAL TABLES

white, assumption (c) at least seems to be called for. The deaths of white infants aged 1 week to 1 month yield increasing rates even without adjustment, and it is somewhat difficult to judge which assumption produces the most plausible rates. However, one would expect these deaths also to be somewhat less completely reported than those occurring after the first year of life, and to require some adjustment.

The age distribution of deaths of white infants in the period 1939–1941 was 31 percent under 1 day, 20 percent from 1 day to 1 week, and 49 percent from 1 week to 1 year. As indicated in the foregoing discussion, it may be assumed for illustrative purposes on the basis of table AF that the percent adjustment required for incomplete reporting of infant deaths was related as follows to the corresponding percent adjustment for births:

Age at death	Number of times the percent adjust- ment for births
Under 1 day	$\frac{1}{2}$
1 day to 1 week	1
1 week to 1 year	$\frac{1}{2}$

This gives for the average percent adjustment for incomplete reporting of white infant deaths  $.31 \times 1.5 + .20 \times 1 + .49 \times 0.5$ , or approximately 91 percent<sup>4</sup> of the corresponding percent adjustment for white births. Since reporting of white births was found to be about 94 percent complete (corresponding to an

TABLE AF.—DEATHS UNDER 1 MONTH PER 1,000 ADJUSTED BIRTHS, BY AGE AND RACE, 1939–1941, ON VARIOUS ASSUMPTIONS AS TO THE COMPLETENESS OF DEATH REGISTRATION, FOR GROUPS OF STATES ARRANGED ACCORDING TO THE COMPLETENESS OF BIRTH REGISTRATION

	WHITE <sup>1</sup>					NONWHITE <sup>2</sup>

Assumption (b)	7.9	8.0	8.7	9.1	9.6	13.4	12.8	12.8
Assumption (c)	8.0	8.1	8.8	9.4	10.3	13.9	13.9	16.4
Deaths after 1 week to 1 month:								
Unadjusted	3.7	3.9	4.2	5.0	5.2	7.8	8.6	7.8
Adjusted <sup>5</sup> according to:								
Assumption (a)	3.7	3.9	4.3	5.2	5.6	8.2	9.4	9.4
Assumption (b)	3.8	4.0	4.6	5.1	6.1	8.5	10.3	11.1
Assumption (c)	3.8	4.0	4.4	5.7	6.5	8.8	11.2	12.3

<sup>1</sup> The States of Arizona, New Mexico, and Texas were omitted from the computation for white lives. See text, p. 104.

<sup>2</sup> Those States reporting less than 500 births of nonwhites in 1939–1941 were omitted from the computations. See footnotes to table AB, p. 102.

<sup>3</sup> Higher numbers indicate less complete registration of births.

<sup>4</sup> Assumptions (a), (b), and (c) suppose that the percent adjustment needed to correct for incompleteness of reporting of deaths in each State in the indicated age period is, respectively, 90, 100, and 150 percent of that required for births in the same State.

<sup>5</sup> Strictly speaking, the proportions of infant deaths occurring in the three age periods used in this calculation should be based on total infant deaths (after adjustment for underreporting). Allowance for this factor would slightly increase the resulting average.

adjustment of 6.4 percent for incomplete reporting, see table AC), this would imply that white infant deaths were about 94.5 percent completely reported.

Similarly, the age distribution of nonwhite infant deaths was 22 percent under 1 day, 18 percent from 1 day to 1 week, 13 percent from 1 week to 1 month, and 47 percent from 1 month to 1 year; and the required percent adjustment for incomplete reporting of deaths of nonwhite infants may be assumed to be related as follows to the corresponding percent adjustment for births:

Age at death	Number of times the percent adjust- ment for births
Under 1 day	2
1 day to 1 week	$\frac{1}{2}$
1 week to 1 month	1
1 month to 1 year	$\frac{1}{2}$

This would give for the average percent adjustment for incomplete reporting of nonwhite infant deaths  $.22 \times 2 + .18 \times 1.5 + .13 \times 1 + .47 \times 0.5$ , or approximately 107.5 percent<sup>4</sup> of the corresponding percent adjustment for nonwhite births. Since reporting of nonwhite births was found in 1940 to be about 82 percent complete, this would mean that on the assumptions made deaths of nonwhite infants were slightly under 81 percent complete. These assumptions are, of course, rough, and such a calculation can be no more than suggestive; however, it does indicate that, in the absence of accurate information on the completeness of registration of infant deaths, it is not unreasonable to assume that for the first year of life taken as a whole the percent completeness of registration of white deaths is the same as that of white births. This assumption is probably as accurate as could be expected with the meager information available, and leads to some simplification in the numerical computation. Accordingly, it was adopted in the preparation of the life tables in this volume. As a matter of convenience, it was used for nonwhites as well as whites, although a somewhat larger correction for nonwhites might be justified.

It should be pointed out that although this assumption is considered appropriate for the data of the United States as a whole, this does not imply that it could properly be employed for separate States, areas, or regions. It is probable that the relationship between the completeness of registration of births and that of infant deaths varies widely in different localities. It is likely, for example, that in highly urban areas where registration is a well established practice, registration of infant deaths is more complete than birth registration. On the contrary, there are indications that the reverse is true in rural areas. Such an indication is found, for example, in the comparison of infant mortality rates by population groups classified according to size.<sup>5</sup> Although these rates tend, in general, to

<sup>4</sup> See, for example, Forrest E. Linder and Robert D. Grove, *Vital Statistics Rates in the United States, 1900–1940*, table 28, p. 578, Government Printing Office, Washington, D. C., 1943.

## PRELIMINARY ADJUSTMENT OF DATA

107

increase steadily with diminishing population size, the rates for rural areas are usually somewhat lower than those for the smallest urban places.<sup>6</sup> It is doubtful if this can be wholly explained on the basis of faulty allocation by residence, since the rates are based not on census populations but on births, which should be affected by errors in allocation in the same direction as infant deaths.

**Method of adjustment of infant data**

Inasmuch as the statistics of births and infant deaths were assumed to be equally complete, mortality rates at age 0 were obtained directly from the reported figures. However, as previously stated, the populations at ages 1 to 4 used in determining the number exposed to risk at those ages were not obtained from the census, but were calculated from birth and death statistics. To the extent that they entered into the calculation of populations at these subsequent ages, the statistics of births and infant deaths required some adjustment. The method followed was to compute, from reported figures only, the number of survivors to the exact age of 1 year from each year's births, and then to increase this number of survivors by the desired percentage before extending the calculations to higher ages. The method of determining the adjustment factors to be applied to the number of survivors at age 1 will now be described.

On first consideration, it might appear that the percents of completeness of birth registration obtained from the birth registration study could be used as divisors to obtain the corrected number of survivors. However, such a procedure would not be consistent with the assumptions being made in connection with ages 5 and above. At these ages it is not assumed that the census figures and the registered deaths are 100 percent complete, but rather that both have the same percent of incompleteness. Since it is not considered that deaths at ages 1 to 4 are reported any more completely than those at ages 5 and above, the populations to be used in rate computations at ages 1 to 4 should not be corrected to a higher degree of completeness than the census populations at ages 5 and over, if a consistent series of mortality rates is to be produced.

In order to determine the proper adjustment factors, a calculation was made, by two independent methods, of the survivors to exact age 1 out of the births corresponding to the 1940 census population at each single year of age from 1 to 9, inclusive. For example, the native population at age 5 (that is, between the fifth- and sixth birthdays) on the census date, April 1, 1940, are survivors of babies born in the year April 1, 1934, to April 1, 1935. The survivors to exact age 1 of this group of births were estimated (a) by subtracting from the reported births of that period the reported infant deaths occurring among this group of lives and (b) by adding to the native population aged 5 on April 1,

1940, as enumerated in the census, the reported deaths among this group of lives after age 1, but before April 1, 1940. Similar calculations were made for the groups at each of the other ages under 10 in the 1940 census. Table AG shows the results, which are given separately for the three racial groups: whites, Negroes, and other races. It will be observed that the ratio of estimate (a) to estimate (b) falls sharply from birth to age 3, but from age 3 to age 9 merely fluctuates without showing any consistent trend. It shows, however, a marked tendency to be low at even ages and high at odd ages. This suggests that the fluctuation may be principally due to preference for certain ages in the census and that the ratio might be very nearly constant except for this disturbance. At the very young ages, where the ratio is particularly high, the census enumeration is known to be markedly deficient.

TABLE AG.—COMPARISON OF SURVIVORS TO AGE 1 AS ESTIMATED BY TWO METHODS. UNITED STATES, 1930-1939

<sup>1</sup> Survivors to Apr. 1, 1940.

<sup>2</sup> 1940 census population under 1 year of age.

An average ratio was therefore obtained for each racial group based on the totals of estimates (a) and (b) for the entire age group 3 to 9 in 1940. These average ratios (also shown in table AG) were then used as divisors, in the construction of the life tables, to

\* The suggestion has sometimes been made that this may be a genuine phenomenon. See, for example, Herbert J. Sommers, *Infant Mortality in Rural and Urban Areas*, Public Health Reports, vol. 57, No. 40, p. 1498, October 1942.

## UNITED STATES LIFE TABLES AND ACTUARIAL TABLES

inflate the number of each group of survivors to age 1, as calculated from births and deaths, to the general level of completeness of the census. The populations at age 1, 2, 3, and 4 used in the actual life table calculations were derived from age 1 survivors adjusted in this manner.

In this method of adjustment it is implicitly assumed that the completeness of birth registration, relative to that of enumeration in the census, did not improve during the decade 1930 to 1940. Similar calculations were also made on the assumption of a progressive improvement in birth registration during the decade, adjusting the reported births of earlier years up to the level of completeness of 1940. This produced a series of ratios (of survivors calculated by the two methods) decreasing with increasing age, which would imply that the enumeration in the 1940 census at ages under 10 became less complete with advancing age. This seems absurd; but, on the other hand, it appears unlikely that there was no improvement during the decade in the completeness of birth registration. As the number of deaths entering into the calculation is small in relation to the total survivors, the completeness of death registration is not an important factor. In view of these inconsistencies in the data, it seemed expedient to adopt the simplest course and assume, for this purpose, no change during the decade in the completeness of birth registration.

#### Adjustment for incomplete reporting of infant deaths by subdivisions of the first year of life

Statistics of infant deaths for subdivisions of the first year of life were used in computing life table values for such subdivisions, as will be explained later.<sup>7</sup> It has already been mentioned that neither births nor infant deaths were corrected for underreporting in obtaining mortality rates for the first year of life as a whole, the assumption being made that reported statistics of births and of deaths under 1 year of age are equally complete. Since births were assumed to be deficient in the proportions indicated in table AC, this is equivalent to the assumption that total infant deaths are deficient in the same proportions. However, in dealing with subdivisions of the first year, consideration must be given to any age variation *within* the year in the assumed completeness of death reporting. It has already been stated that the evidence indicates a progressive improvement with increasing age from birth up to the first birthday. In order to give effect to this condition, the admittedly rough assumption was made that the *percent* addition which must be made to the reported deaths at any specific age during the first year of life in order to correct for underregistration is directly proportional to the time interval remaining up to the first birthday. It can only be said for this assumption that it gives plausible results, and, in the absence of any real information as to the specific age

incidence of nonreporting of infant deaths, it seems as reasonable as any other assumption which might be made. Naturally, the resulting life table values for subdivisions of the first year cannot be considered as reliable as those for integral ages, but it is believed that they serve a useful purpose in indicating the general trend of mortality and survival in this important period of life; and, in any case, these values are not an essential part of the life table. The values for integral ages were computed quite independently of the assumption just stated, the supplementary values for the first year being then inserted at a later stage.

In carrying out the numerical work under this assumption as to nonreporting of infant deaths, the remaining portion of the first year of life was taken, for each of the subdivisions in which infant deaths are tabulated, as the interval of time between the *middle* of such subdivision and the end of the year of age. The length of the entire year was taken as 365½ days, this being the average length of the three calendar years (1939–1941) covered by the experience. For this purpose, 1 month was regarded as being exactly one-twelfth of a year or 30½ days. Table AH shows, on these assumptions, the number of days remaining in the year after the middle of each subdivision of the first year of life. The assumption that the *percent* additions required in the various age periods are proportional to these numbers implies that the *actual numbers* of deaths assumed to be unreported will be proportional to the products obtained by multiplying the time intervals indicated in table AH by the numbers of deaths actually reported in the corresponding age periods. These products were obtained separately by sex and for whites, Negroes, and other races; and in proportion to them the total number of deaths assumed unreported for the entire first year of life was distributed by age, in each of the six classifications. These total numbers, in turn, were obtained by dividing the total deaths reported for the year by the proportion assumed to be

## PRELIMINARY ADJUSTMENT OF DATA

109

registered, as indicated in table AC, and subtracting the reported number from the result. Within each classification by race, the same percents of completeness were assumed to hold for both males and females. The figures resulting from this adjustment are shown in part III of table AM, except those for "other races" aged 1 to 11 months, in which case a further adjustment was made as described later.

## Redistribution of "other races" deaths under 1 year of age

The reported deaths for subdivisions of the first year of life for the group of nonwhites other than Negroes show serious irregularities, due apparently to the small size of the experience, which, if not adjusted for, would cause a marked lack of smoothness in the life table values. Accordingly, the deaths occurring at ages between 1 month and 1 year, after being adjusted for assumed underreporting, were redistributed by fitting a second degree curve to the monthly values by the method of least squares, subject to the condition that the total for the 11-month period must be reproduced. If  $y_x$  denotes the original, and  $y'_x$  the adjusted number of deaths at the age of  $x$  months, and if  $x'$  stands for  $x-6$ , then it is found by applying the usual least squares criterion that  $y'_x$  is given by the equation:

$$y'_x = a + bx' + cx'^2$$

where

$$a = \frac{1}{429} (89\sum y_x - 5\sum x'^2 y_x)$$

$$b = \frac{1}{110} \sum x' y_x$$

$$c = \frac{1}{858} (\sum x'^2 y_x - 10\sum y_x)$$

all the summations being from  $x=1$  to 11; that is, from  $x'=-5$  to +5. Writing the equation in terms of  $x'$  rather than  $x$  makes the 11-month total a symmetrical expression and leads to results of a simpler form than would otherwise be obtained. Table AJ shows the calculated number of deaths in each of the 11 months, both before and after the least squares adjustment.

TABLE AJ.—LEAST SQUARES ADJUSTMENT OF DEATHS OF OTHER RACES<sup>1</sup> AT AGES 1 TO 11 MONTHS: UNITED STATES, 1939-1941

<sup>1</sup> All except white and Negro.

## Unreported ages at death

For a small proportion of deaths the age is not specified. In order not to underestimate the total mortality, these deaths must be distributed in some manner among the various age groups. The method used was to divide them in proportion to the numbers actually reported in each age group. While this is probably not strictly correct, the entire number of deaths involved is so small a fraction of the total that little error could result. This problem does not arise in connection with the population figures, because in the 1940 census probable ages were assigned by a special process to all persons whose age was not reported, so that no unknown ages appear in the final tabulations.<sup>8</sup>

## Estimation of July 1, 1940, populations

For ages 5 and above, the populations required in the construction of life tables for the 3-year period 1939-1941 are those at the middle of the period: that is, on July 1, 1940. Since the census was taken as of April 1, 1940, an adjustment is necessary to arrive at the July 1, 1940, figures. For this purpose the following formula was applied to each subdivision of the population by race and sex for each 5-year age group from age 5 to age 100, and for the final group consisting of ages 100 and over. Estimates for the age group 3-4 years were also obtained, to be used in the interpolation process as described later.

$$P_{z/z+n-1}^{4/1} = P_{z/z+n-1}^{4/1} - k D_{z/z+n-1}^{1940} + \frac{1}{4}(P_{z-1}^{4/1} - P_{z+n-1}^{4/1}) + M_{z/z+n-1}$$

Here,  $P_{z/z+n-1}^{4/1}$  denotes the population on April 1, 1940, at ages  $z$  to  $z+n-1$ , inclusive (that is, between exact age  $z$  and exact age  $z+n$ ); and  $P_{z/z+n-1}^{4/1}$  denotes the corresponding population on July 1, 1940. Similarly,  $P_{z-1}^{4/1}$  denotes the April 1 population at age  $z-1$ , and  $P_{z+n-1}^{4/1}$  denotes the April 1 population at age  $z+n-1$ .  $D_{z/z+n-1}^{1940}$  denotes the number of reported deaths occurring in 1940 at ages  $z$  to  $z+n-1$ ; and  $M_{z/z+n-1}$  denotes the estimated net immigration (positive or negative) during the period April 1 to July 1, 1940, at ages  $z$  to  $z+n-1$ . The symbol  $k$  denotes the ratio, for both sexes and all races combined, of the reported deaths occurring in April, May, and June, 1940, to the total for the year.

The term  $k D_{z/z+n-1}^{1940}$  represents the estimated deaths occurring in the particular age group between April 1 and July 1, 1940. This approximation had to be used, as deaths were not tabulated simultaneously by month of occurrence and by race or sex. The term  $\frac{1}{4}(P_{z-1}^{4/1} - P_{z+n-1}^{4/1})$  is an adjustment for the fact that in the 3 months between April 1 and July 1 some individuals passed out of the group by reaching age  $z+n$ , while others entered from the next lower age group by reaching age  $z$ . In dealing with the final age group "100 and over," this term reduced to merely  $\frac{1}{4}P_{99}^{4/1}$ , and the subscript " $z/z+n-1$ " in the other terms

<sup>8</sup> U. S. Bureau of the Census, *Sixteenth Census of the United States: 1940, Population, vol. II, Characteristics of the Population, Part I*, p. 9, Government Printing Office, Washington, D. C., 1943.

## UNITED STATES LIFE TABLES AND ACTUARIAL TABLES

was interpreted as "100 and over." The net immigration was estimated on the basis of information furnished by the Immigration and Naturalization Service, Department of Justice. For the white population, the migration adjustment never exceeded 0.06 of 1 percent of the corresponding enumerated population in any classification.

While the total nonwhite population was available by single years of age, Negroes were tabulated separately only by 5-year age groups up to age 75 and also for a few selected single years of age under 21. The single age figures for Negroes were obtained by assuming that, for each sex separately, the ratio of Negroes to total nonwhites was the same in each single year of age as in the smallest age group containing that year of age for which separate figures for Negroes and other nonwhites were available. In each classification, estimated figures for "other races" were obtained by subtracting Negroes from total nonwhites. A further difficulty was encountered in that the migration estimates used were furnished only for total nonwhites, and not for Negroes separately. As the movement of Negroes into and out of the United States is believed to be exceedingly small, and as the migration estimates for total nonwhites were small in any case, never reaching 100 for either sex in any 5-year age group, they were assumed to relate wholly to races other than Negroes, no migration adjustment being made in the Negro populations.

The estimates of July 1, 1940, population resulting from the application of the above formula are shown in part II of table AM, except those for Negroes between ages 55 and 70, in which case a further adjustment was made as explained in the next subsection. These estimated populations differ only slightly from those previously published by the Bureau of the Census.<sup>9</sup> It was decided not to use the previously published estimates in the construction of the life tables because they were based on a graduated, or smoothed distribution by single years of age of the April 1 population. While such a procedure was entirely appropriate in preparing population estimates for general use, it was felt that, in the construction of the life tables, the smoothness of the rates of mortality was adequately provided for by the graduation of the rates themselves,<sup>10</sup> and that there were some objections to graduating the enumerated populations. The single year populations, since they arise, in the beginning, from fluctuating numbers of annual births, cannot be expected to form a perfectly smooth series, and any genuine irregularities will be reflected also in the death statistics, so that the smooth progression of the rates of mortality will not be disturbed. Moreover, this appears to be true also, in large measure, of the irregularities which are not genuine, since the analysis of digit preference later in this report<sup>11</sup>

indicates that, in the usual system of 5-year age grouping (5-9, 10-14, etc.), errors of this type in the populations and deaths tend to cancel out in the computation of mortality rates. Therefore, if the populations were partially smoothed, without subjecting the death statistics to some similar treatment, the result might only be to diminish the smoothness of the mortality rates.

## Special adjustment of Negro data

Both population and death statistics in the neighborhood of age 65 show evidence of substantial misstatement of age. In the case of the data for Negroes, this error appeared sufficiently marked to seriously affect life table values. This condition is brought out in table AK in which the 1940 Negro populations actually enumerated in the various age groups are compared with those expected on the basis of the 1930 populations of the same groups of individuals (then 10 years younger) and the deaths of the intervening period. It will be noted that while these population figures show, on the whole, a steady decrease with advancing age, the *enumerated* 1940 populations level off sharply at age 65. The 1930 figures do not show any such tendency. Moreover, the *expected* 1940 populations, from the 1930 enumeration and the deaths during the decade, are free from the leveling off effect. This strongly suggests an overstatement in the 1940 census of the age groups just beyond 65 at the expense of those just under that age. This phenomenon is probably attributable to the enactment of social security legislation providing benefits to persons over 65.

TABLE AK.—COMPARISON OF NEGRO POPULATIONS IN CERTAIN AGE GROUPS: UNITED STATES, 1930 AND 1940

[Numbers given in thousands]

Age in 1930 (1)	Age in 1940 (2)	Population enumerated in 1930 (3)	1940 population estimated from 1930 population and deaths (4)	Population enumerated in 1940 (5)	Discrepancy in 1940 estimates (4)-(5)
40-44	50-54	339	264	283	-19
45-49	55-59	323	245	207	+38
50-54	60-64	278	207	154	+53
55-59	65-69	174	109	152	-43
60-64	70-74	133	76	84	-8
65-69	75-79	83	40	40	0
70-74	80-84	51	20	19	+1
75-79	85-89	29	7	9	-2
FEMALE					
40-44	50-54	448	285	267	+18
45-49	55-59	307	242	190	+52
50-54	60-64	227	166	142	+27
55-59	65-69	135	83	145	-62
60-64	70-74	100	63	70	-16
65-69	75-79	72	36	42	-6
70-74	80-84	48	22	22	0
75-79	85-89	29	10	11	-1

The conclusion that such misstatement of age has occurred is reinforced by the observation that mortality rates calculated from the reported data without adjustment also level off sharply at 65, in the case of the females actually showing a temporary decrease

<sup>9</sup> U. S. Bureau of the Census, *Estimated Population in Continental United States, by Age, Color, and Sex: 1940-1948*, Population—Special Reports, Series P-44, No. 9, 1944.

<sup>11</sup> See pp. 120-122.

## PRELIMINARY ADJUSTMENT OF DATA

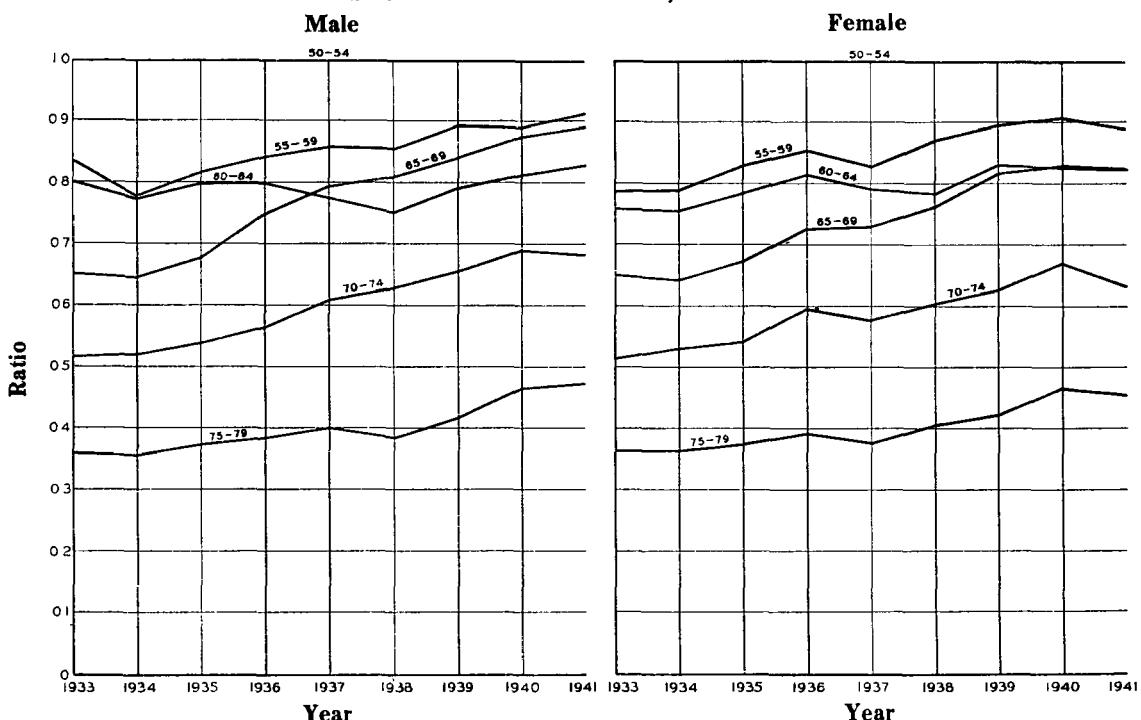

111

with increasing age. There is evidence also that the death statistics have been affected in the same way. This is indicated by figure 12, which shows the trend for the period 1933-1941 of the ratio of Negro deaths in certain selected age groups to those occurring in the same year in the age group 50-54. The age groups selected extend from age 55 to age 80. The general tendency of each of these ratios over any fairly long period is to increase gradually, because of the steadily increasing proportion of the population in the older age groups. In every year of the period covered by the graph, the Negro deaths by 5-year age groups have reached a maximum in the group 50-54, and prior to 1937 have decreased steadily thereafter to the end of life. However, in 1937 and each subsequent year, the reported deaths for Negro males in the age period 65-69

it seemed advisable to make a preliminary redistribution of the Negro populations and deaths between 55 and 70. After experimenting with various empirical methods of redistribution, the one described in the next paragraph was adopted as giving the most plausible results.

From the estimated July 1, 1940, populations, obtained as previously described, the ratio of the Negro population 50 and over to the corresponding white population was obtained, for males and females separately. Similar ratios were obtained for the population 55 and over, 60 and over, and so on up to and including 75 and over: a total of six ratios for each sex. The calculated ratios for ages 60 and over and 65 and over were rejected, and corrected values of these ratios were obtained by interpolation from the remaining four

FIGURE 12.—RATIO OF NEGRO DEATHS IN SELECTED AGE GROUPS TO NEGRO DEATHS AT AGES 50-54 IN THE SAME YEAR: UNITED STATES, 1933-1941

have exceeded those in the group 60-64. In this connection it will be remembered that the Social Security Act was enacted in 1935 and that State old-age assistance programs as provided by the act did not go into operation until 1936 or, in a few States, even later. In the case of Negro females the effect is less noticeable, although the number of deaths in these two age groups began in 1937 to move closer together, and in 1940 there was actually a larger number in the group 65-69. In view of the magnitude of this disturbance,

ratios, using Waring's formula.<sup>12</sup> By applying these corrected ratios to the white populations 60 and over and 65 and over, corrected Negro populations were obtained. By inserting these corrected values in the original series of Negro populations 50 and over, 55 and over, etc., and differencing, corrected populations by 5-year age groups were obtained. By this method, only

<sup>12</sup> Also known as Lagrange's formula. See E. T. Whittaker and G. Robinson, *The Calculus of Observations*, second edition, pp. 28-32, Blackie and Son, Ltd., London and Glasgow, 1937; also T. N. E. Greville, *A Generalization of Waring's Formula*, Annals of Mathematical Statistics, vol. 15, No. 2, pp. 218-219, June 1944.

## UNITED STATES LIFE TABLES AND ACTUARIAL TABLES

the figures for the age groups 55-59, 60-64, and 65-69 are changed, and these automatically add to the original total for the entire 15-year age period. The method does not assume that the white and Negro populations have similar age distributions, but merely that the ratio between them progresses fairly smoothly by age. The Negro deaths reported in these three age groups were redistributed by relating them to the corresponding white deaths in the same manner. Table AL shows the original figures for Negro populations and deaths and also the adjusted figures obtained in the redistribution. For comparison, the figures for the two adjacent age groups on each side are also shown.

#### Estimation of foreign-born population under 5

As will be explained later when the method of calculating mortality rates under 5 is described, the distribution by nativity of the 1940 population in this age group, separately by sex, race, and single years of age, was required. For whites, the census tabulations give, for males and females separately, the number of foreign-born under 1 year, the number at ages 1-4, and the number at age 5. Single year figures for both sexes were obtained by assuming that the figures for single years starting with age 1 and ending with age 5 formed an arithmetic progression. This assumption was suggested by a study of the data of previous censuses, in which the complete detail was available. The resulting values were then distributed by sex in the same ratio as the entire age group 1-4, and rounded to add to the correct total.

Nativity was tabulated for Negroes by 5-year age groups only, and the foreign-born Negroes under age 5 were distributed by single years of age on the assumption that, for each sex separately, the numbers for the first 5 years of age formed an arithmetic progression in which the common difference was equal to the number under 1 year of age. In the case of the remaining races, foreign-born were given by age only for Chinese and Japanese. Hence, it was assumed that there were no foreign-born under age 5 of races other than white,

Negro, Chinese, and Japanese. In actual fact, the number of such children is believed to have been very small. The estimated native population in each classification was, of course, obtained by subtracting the estimated foreign-born from the total.

#### B. CALCULATION OF THE RATES OF MORTALITY

The description of the process of obtaining rates of mortality divides itself naturally into two main parts, corresponding to ages 0 to 4 and ages 5 and over, since the methods used in the two cases were very different. In connection with the calculation of mortality rates for ages 0 to 4, two subordinate topics are discussed under separate subheadings. These are (1) the derivation of separation factors for estimating the distribution of deaths by calendar year of birth, and (2) the adjustment of the mortality rates to allow for the effect of migration.

Basically, the method employed in obtaining rates at ages 5 and over consisted of three steps. First, populations and deaths were estimated by interpolation for the middle age of each of the 5-year age groups in which the data were tabulated. Secondly, rates of mortality for these middle ages (at 5-year intervals) were computed from the interpolated populations and deaths. Finally, osculatory interpolation was applied to the mortality rates derived in the second step in order to obtain rates for all ages. In the discussion which follows, each of these three steps is treated under a separate subheading. Additional subsections are devoted to (1) a justification of the basic procedure just described, as against other procedures which have sometimes been employed, and (2) a description of the tests which were applied to the final rates of mortality in order to be sure that the graduation was satisfactory. Further subsections deal with two digressions from the main theme: (a) an analysis of preferences shown in the reporting of age for figures ending with certain digits and the effect of this bias on mortality rates, with reference to the selection of a particular way of combining single ages into 5-year age groups; and (b) the method used in obtaining mortality rates at the very old ages, where the ordinary methods fail to give satisfactory results, because of unreliable age reporting and the small volume of data.

All the basic data actually used in the construction of the various life tables are given in table AM. Part I of that table contains the data required in the computation of mortality rates for ages 0 to 4, inclusive; while part II contains the data used in deriving mortality rates for ages 5 and over. Part III contains certain additional data required in obtaining life table values for subdivisions of the first year of life.

## CALCULATION OF RATES OF MORTALITY

115

## Basic process for obtaining mortality rates at ages 0 to 4

The basic equation employed in obtaining mortality rates at ages 0 to 4 is based on the interpretation of the rate of mortality as a probability of death. For example, the rate of mortality<sup>13</sup> at age  $x$ , denoted by  $q_x$ , can be regarded as the probability that a person exactly  $x$  years old will die before reaching exact age  $x+1$ . Similarly, the complement  $p_x = 1 - q_x$  represents the probability that an individual exactly  $x$  years of age will survive to exact age  $x+1$ . In order to facilitate its calculation from the data available,  $p_x$  may be expressed as the product of two separate probabilities. Thus:<sup>14</sup>

$$p_x = {}_a p_x \cdot {}_s p_x$$

where  ${}_a p_x$  denotes the probability that an individual alive at exact age  $x$  will survive to the end of the calendar year in which this exact age was attained, and  ${}_s p_x$  denotes the probability that an individual who is alive at the end of the calendar year in which he attained age  $x$  will survive to exact age  $x+1$ . It follows that:

$$q_x = 1 - {}_a p_x \cdot {}_s p_x \quad (10)$$

this being the basic formula employed in computing mortality rates at ages 0 to 4. In order to derive expressions for the partial probabilities  ${}_a p_x$  and  ${}_s p_x$  in terms of the data as given, the following special symbols will be employed:

$E_x^z$  denotes the number reaching exact age  $x$  during the calendar year  $z$ .

$P_x^z$  denotes the number living on January 1 of the year  $z$  whose age in completed years is  $x$ .

$D_x^z$  denotes the number dying in the year  $z$  whose age in completed years at the time of death is  $x$ .

${}_s D_x^z$  denotes that portion of  $D_x^z$  consisting of cases in which exact age  $x$  was reached during the year  $z$ .

${}_a D_x^z$  denotes that portion of  $D_x^z$  consisting of cases in which exact age  $x$  was reached during the year  $z-1$ .

$E_x$  denotes the total number reaching exact age  $x$  during the entire period of observation, which is assumed to be an integral number of years.

$P_x'$  denotes the total number who, after attaining exact age  $x$  during the period of observation, are still alive at the end of the year in which exact age  $x$  was attained.

$P_x''$  denotes the total number who are alive at the end of the year in which age  $x$  was attained, and whose  $(x+1)$ th birthday falls within the period of observation.

<sup>13</sup> The rates of mortality shown in the life tables which appear in this volume (except in the case of tables 14, 25, and 38) are values of  $1,000q_x$ , the rate of mortality per 1,000 survivors at age  $x$ . However, in developing the mathematical theory of the life table, it is more convenient to use the rate of mortality per single survivor.

<sup>14</sup> The notation employed in this development follows, with slight modifications, that of Hugh H. Wolfenden in *Population Statistics and Their Compilation (Actuarial Studies, No. 3)*, pp. 70-84, Actuarial Society of America, New York, 1925. The basic formula (10) given here is Wolfenden's formula (12), p. 76.

$u$  and  $v$  denote, respectively, the first and last years included in the period of observation.

Certain relationships between these symbols are immediately apparent. For example,

$$E_x^z - {}_a D_x^z = P_x^{z+1} \quad (11)$$

and

$$P_x^z - {}_s D_x^z = E_x^{z+1} \quad (12)$$

If birth and death statistics were available in the necessary detail, it would be possible, by successive applications of formulas (11) and (12), to obtain values of  $E_x^z$  and  $P_x^z$  for any desired ages. It is to be noted that  $E_0^z$  denotes the number reaching age 0: that is, the number of births, in the year  $z$ .

For example, suppose it is desired to find the number alive on January 1, 1940, at age 4 in completed years, and also the number reaching exact age 5 in 1940. Anyone whose age in completed years on January 1, 1940, is 4, or who reaches exact age 5 in 1940, must have been born in 1935. Therefore, one would start with  $E_0^{1935}$ , the number of births occurring in that year. Formula (11) gives:

$$E_0^{1935} - {}_a D_0^{1935} = P_0^{1936}$$

and formula (12) gives:

$$P_0^{1936} - {}_s D_0^{1936} = E_1^{1936}$$

By continuing in this fashion and applying formulas (11) and (12) alternately, the desired values would eventually be reached, provided, of course, the necessary birth and death statistics are available.

It is obvious from the definition of  $E_x$ ,  $P_x'$ , and  $P_x''$  that

$$E_x = \sum_{z=u}^v E_x^z \quad (13)$$

$$P_x' = \sum_{z=u+1}^{v+1} P_x^z \quad (14)$$

and

$$P_x'' = \sum_{z=u}^v P_x^z \quad (15)$$

Finally, the values of the partial probabilities  ${}_a p_x$  and  ${}_s p_x$ , on the basis of the experience which is being employed, are given by:

$${}_a p_x = \frac{P_x'}{E_x} \quad (16)$$

and

$${}_s p_x = \frac{E_{x+1}}{P_x''} \quad (17)$$

Formulas (11) to (17) and formula (10) would seem to provide the means of computing mortality rates up to any age desired, if adequate birth and death statistics are available. There remain, however, two difficulties. In the first place, deaths are not ordinarily tabulated so as to give the separate parts denoted by  ${}_a D_x$  and  ${}_s D_x$ ; and, secondly, the effect of migration has been ignored. The methods employed in order to overcome these two

## 116

## UNITED STATES LIFE TABLES AND ACTUARIAL TABLES

difficulties form the subject of the next two subsections. However, it will be useful, before taking up these rather technical points, to give a numerical illustration of the application of the formulas just derived. In this illustration, the required values of  $\_D_x$  and  $\_D_x$  will be given without explanation as to how they were obtained; and, inasmuch as the correction for migration was made as a final adjustment in the mortality rates, after the calculations had been otherwise completed, the consideration of this point can easily be postponed.

Another point which needs to be mentioned at this time concerns the method of applying the correction for underreporting of births and infant deaths. Since these were assumed to be equally complete,<sup>15</sup> the rates of mortality at age 0 were obtained from registered figures without applying any correction. To this end, the calculations were begun by taking as the values of  $E_0^*$  the number of births registered in the various years. By the subtraction of registered deaths, values of  $P_0^*$  and  $E_1^*$  were obtained. The values of  $q_0$  were computed from these three sets of quantities as indicated by formulas (13) to (17) and formula (10). Next, the values of  $E_1^*$  were corrected for underreporting by dividing by the ratios derived for that purpose,<sup>16</sup> which were based on comparison with census populations in the age period 3 to 9. These adjusted values of  $E_1^*$  were taken as the starting point in obtaining corrected values of  $P_2^*$  and  $E_2^*$  for subsequent ages, it being assumed that deaths occurring at ages 1 and over required no correction. Mortality rates at ages 1 to 4 were then computed entirely on the basis of corrected figures.

The calculation of mortality rates at ages 0 to 4 for white males will be taken as a numerical illustration of

the process. The registered births for each of the 8 years 1934 to 1941 are given in part I of table AM, page 113. Those values of  $\_D_x$  and  $\_D_x$  which will be needed in the computations are shown in table AN. The calculation of the values of  $P_0$  and  $E_1$  and the adjustment of  $E_1$  for underreporting are shown in table AO. For the births of the years 1934 to 1937, the number of survivors to the end of the year of birth is not required, since the children concerned will have reached age 1 before January 1, 1939, the commencement of the period of observation. Therefore, for the births of these years, the total number of infant deaths to be subtracted, although the sum of two figures in table AN, is shown as a single figure in table AO. It will be noted that each of these totals contains deaths occurring in two different calendar years. In each case, the number of survivors to exact age 1 of the registered births is corrected for underregistration by dividing by .9551, the ratio previously derived for that purpose.<sup>17</sup>

TABLE AN.—DEATHS OF WHITE MALES AT AGES 0 TO 4, BY AGE AND YEAR OF DEATH, SEPARATED ACCORDING TO WHETHER DEATH OCCURRED IN THE SAME YEAR AS THE LAST BIRTHDAY ATTAINED, OR IN THE FOLLOWING YEAR: UNITED STATES, 1934-1941

TABLE AO.—NUMBER OF REGISTERED BIRTHS OF WHITE MALES, NUMBER SURVIVING SPECIFIED PERIODS, AND ADJUSTMENT FOR UNDERREPORTING, BY YEAR OF BIRTH (z): UNITED STATES, 1934-1941

	1934	1935	1936	1937	1938	1939	1940	1941
Registered births ( $E_0^*$ )	975,804	969,916	966,332	991,356	1,030,398	1,019,021	1,064,067	1,133,394
Deaths to be subtracted ( $\_D_0$ )	49,039	45,196	46,658	44,654	44,542	41,165	43,138	43,423
Survivors to end of year of birth ( $P_0$ )	(1)	(1)	(1)	(1)	985,850	977,856	1,020,929	1,088,971
Deaths to be subtracted ( $\_D_0 + \_D_1$ )	11,228	10,312	10,886	9,579	9,036	8,339	8,768	(1)
Survivors to exact age 1 ( $E_1^{**}$ )	915,537	914,408	908,788	937,123	976,820	969,517	1,012,161	(1)
Survivors to exact age 1 (corrected for underreporting)	958,577	957,395	951,511	981,178	1,022,741	1,015,095	1,059,743	(1)

<sup>1</sup> Not needed in life table calculations.

Continuation of the process of subtracting the appropriate groups of deaths, in accordance with formulas (11) and (12), gives the various numbers shown in table AP. In the case of the births of the years 1934 to 1936, the deaths occurring between the attainment of age 1 and January 1, 1939, can be lumped together, as it is not necessary to know the number of survivors on any prior date. It will be noted that the successive death figures to be subtracted from a given year's births form a sort of broken diagonal extending downward and to the right in table AN, consisting of  $\_D_0$  from

the column for the given year itself,  $\_D_1$  and  $\_D_2$  from the column for the following year,  $\_D_1$  and  $\_D_2$  from the column for the next following year, and so on. After January 1, 1939, has been reached, the successive death figures must be subtracted one by one, noting the remainder after each subtraction, until the cohort has been carried to January 1, 1942, after which no further values are needed. The various numbers of survivors shown in table AP are arranged not according to the year of birth, but according to the calendar year in which the indicated exact age is attained, or at the

## CALCULATION OF RATES OF MORTALITY

beginning of which the indicated population exists. In those lines of the table which give values of  $P_z^*$ , the total for 1939-1941 is, of course,  $P_z''$ , while the total for 1940-1942 is  $P_z'$ .

Values of  $\alpha p_z$  and  $\alpha p_z'$  for ages 1 to 4 obtained from the figures in the last two columns of table AP are given in table AQ which also shows the calculation of the mortality rates except for the final adjustment for migration. The calculations for age 0 are not shown, since in that case the adjustment for migration was introduced at an earlier stage in the computation. This point is explained in detail on pages 119 and 120.

In the case of the life tables for combinations of classes such as total whites or total males, the values of  $E_z$ ,  $P_z'$ , and  $P_z''$  for the component parts were combined before computing the partial probabilities of survival, the remainder of the calculation being exactly the same as for the separate classes.

TABLE AP.—NUMBER OF WHITE MALES SURVIVING SPECIFIED PERIODS OF LIFE BETWEEN BIRTH AND AGE 5: UNITED STATES, 1939-1941

CLASS OF SURVIVORS <sup>1</sup>	CALENDAR YEAR IN WHICH INDICATED BIRTHDAY IS REACHED, OR AT THE BEGINNING OF WHICH INDICATED POPULATION EXISTS (2)					
	1939	1940	1941	1942	Total 1939-1941	Total 1940-1942
$E_0^*$	1,022,741	1,015,095	1,059,743	1,052,187	3,097,579	3,088,766
$P_0^*$	977,422	1,019,619	1,012,187	1,056,960	3,006,228	3,003,103
$E_1^*$	975,252	1,017,593	1,010,253	1,054,960	3,023,180	2,998,583
$P_1^*$	943,175	971,780	1,016,224	1,068,919	2,929,180	2,926,632

#### Derivation of separation factors for deaths

In the preceding section, mention was made of the necessity of separating the deaths of each calendar year into two groups according to whether death occurred in the same calendar year as the last birthday attained, or in the following year. This could evidently be accomplished by sorting on the year of birth. To illustrate this, consider the case of children dying in 1940 at age 3. In this group, all those who reached exact age 3 in 1939 were obviously born in 1936, while those who reached exact age 3 in 1940 were born in 1937. However, deaths in the United States are not tabulated by year of birth; and it was therefore necessary to estimate, in each case, the subdivision of  $D_z^*$  into  $D_z^*$  and  $\alpha D_z^*$ .

This is accomplished by employing what may be

called "separation factors." The separation factor, denoted by  $f_z^*$ , is defined as

$$f_z^* = \frac{\alpha D_z^*}{D_z^*} \quad (18)$$

In dealing with death statistics not tabulated by year of birth, it is customary to employ values of this ratio obtained from other data, so that the working formulas are:

$$\alpha D_z^* = (1 - f_z^*) D_z^* \quad (19)$$

and

$$\alpha D_z^* = f_z^* D_z^* \quad (20)$$

Tabulations of deaths from which values of  $f_z^*$  can be obtained directly have never been made in the United States, and are found in only a few countries, notably Germany.<sup>18</sup> Such a tabulation is now being undertaken in the Bureau of the Census based on a 10-percent sample of all 1944 deaths under age 5; and the values derived from it will be available for use in the preparation of future life tables.

It is not always satisfactory to use values of  $f_z^*$  based on the statistics of other countries, particularly if such statistics are, in addition, not very recent, as the values of this ratio have been observed to vary as between different countries and to change markedly over periods of time. Another alternative is to approximate the values of  $f_z^*$  by making use of tabulations of deaths by month of age, if these are available. In the United States, such tabulations have been made in recent years only for the first year of life. However, it is in the first year of life that the values of  $f_z^*$  are most subject to change, so that reliance on values obtained from outside sources is most unsatisfactory. Accordingly, the values of  $f_0^*$  used in connection with the life tables in this volume were all estimated from the tabulations of deaths by subdivisions of the first year of life.

The method of arriving at such estimates is best illustrated by a numerical example. This example will be based on the tabulation of infant deaths for males of all races in 1935. The data to be used are given in table AR. In this table, attention is called to the figures in bold-face type which extend across the table more or less diagonally. It is evident that all the figures below and to the left of the bold-face figures represent deaths of infants born in 1934. Similarly, all the figures above and to the right of the bold-face figures refer to deaths of infants born in 1935. However, the bold-face figures themselves include some deaths of infants born in 1934 and some deaths of infants born in 1935. In the case of all these figures except those which represent deaths in the month of January, it was assumed that an equal number were born in each of the 2 years. When one of these numbers was an odd number, the extra infant was assumed to have been born in the year of death (in this case, 1935).

<sup>18</sup> See U. S. Bureau of the Census, *United States Life Tables, 1890, 1901, 1910, and 1901-1910*, p. 339, Government Printing Office, Washington, D. C., 1921.

## UNITED STATES LIFE TABLES AND ACTUARIAL TABLES

TABLE AR.—DEATHS OF MALES UNDER 1 YEAR OF AGE, BY MONTH OF DEATH AND BY AGE: UNITED STATES, 1935

AGE	Jan.	Feb.	Mar.	Apr.	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.
Total under 1 year	7,145	6,376	6,601	5,740	5,747	5,489	5,413	5,219	4,920	5,107	5,143	5,815
Under 1 day	1,548	1,451	1,610	1,561	1,680	1,689	1,746	1,631	1,405	1,502	1,488	1,470

2 months	431	431	429	347	333	310	268	250	281	324	356	390
3 months	416	352	346	296	293	216	228	202	259	257	261	347
4 months	322	272	270	204	206	239	231	197	190	209	198	237
5 months	267	237	249	189	184	177	171	171	154	159	184	212
6 months	217	253	242	182	186	170	187	146	123	152	149	148
7 months	186	188	220	184	161	155	141	142	128	113	112	142
8 months	158	172	200	151	166	135	133	124	120	110	121	115
9 months	159	162	186	162	170	165	133	107	98	87	93	108
10 months	124	113	141	120	115	118	102	83	73	77	82	112
11 months	160	128	157	111	123	104	8 <sup>a</sup>	105	66	85	62	94

In the month of January, the assumption was made that, within each age period shown,  $\frac{1}{31}$  of the total deaths occurred on each day of the month. In the case of deaths under 1 day, an infant included in this group who was born in 1934 must have died on January 1. However, even among those dying on January 1 at an age under 1 day, some were born in 1935. Therefore it was assumed that  $\frac{1}{2}$  of  $\frac{1}{31}$ , or  $\frac{1}{62}$  of the deaths under 1 day occurring in January were of infants born in 1934. Multipliers for the other age periods under 1 month were obtained by similar reasoning, and are shown in table AS. It will be sufficient to give one further illustration. Those infants dying in January 1935 at the age of 1 week (exact age 1-2 weeks), who were born in 1934 include all those dying in this age interval on January 1 to 7, inclusive, and a portion of those dying on January 8 to 14, inclusive. The number of deaths on January 1 to 7 is assumed to be  $\frac{1}{31}$  of the total for the month. The number occurring on January 8 to 14 is likewise assumed to be  $\frac{1}{31}$ , and it is further assumed that one-half of these are of infants born in 1934. Therefore, the proportion of the total January 1935 deaths at the age of 1 week which are assumed to represent 1934 births is  $\frac{1}{31}$  plus  $\frac{1}{2}$  of  $\frac{1}{31}$ , or  $\frac{2}{62}$ .

By the application of these rules, the estimated total number of deaths under 1 year in 1935 of infants born in 1934 is found to be 14,236 to the nearest integer, while the total number of deaths under 1 year in 1935, irrespective of the year of birth, is 68,805. Therefore, the value of  $f_0^{1935}$  is the quotient of 14,236 by 68,805, or .207.

TABLE AS.—PROPORTION OF JANUARY DEATHS UNDER 1 MONTH ASSUMED TO REPRESENT BIRTHS OF THE PREVIOUS YEAR

Age at death	Under 1 day	1 day	2 days	3 to 6 days	1 week	2 weeks	3 weeks to 1 month
Assumed proportion born in previous year	.162	.362	.562	.1962	.2162	.2562	.5262

However, this value applies to all males of all races combined; and it is desired to obtain values for the different races separately, as  $f_0^x$  is known to vary significantly by race. A difficulty is encountered in

that the tabulation of infant deaths in the United States by age and month of death was further subdivided only by sex prior to 1939; and commencing with that year, even the sex classification was eliminated.<sup>19</sup> However, for all the years involved in the life table calculations, another tabulation was available giving infant deaths for the United States by age, race, and sex (but not by month of death). Separation factors at age 0 by race and sex for the years 1939 to 1941 were obtained by making the assumption that, within each age period, the distribution of deaths by race and sex was the same in each calendar month of death as for the entire calendar year. The values for the years 1934 to 1938 had previously been calculated by a somewhat less refined method, and were not recomputed. The values of  $f_0^x$  actually employed for each of the years 1934 to 1941 are given in table AT.

TABLE AT.—SEPARATION FACTORS AT AGE 0 (VALUES OF  $f_0^x$ ) BY RACE AND SEX: UNITED STATES, 1934-1941

YEAR	WHITE		NEGRO		OTHER RACES	
	Male	Female	Male	Female	Male	Female
1934	0.187	0.198	0.216	0.226	0.291	0.319
1935	.199	.210	.210	.215	.302	.304
1936	.181	.191	.216	.221	.275	.315
1937	.196	.204	.214	.219	.277	.310
1938	.177	.188	.222	.223	.296	.332
1939	.180	.191	.226	.231	.304	.348
1940	.162	.174	.202	.209	.270	.320
1941	.168	.180	.223	.230	.328	.310

As no data were available for the United States from which separation factors for ages 1 to 4 could be estimated, the values employed by Glover<sup>20</sup> were again used. These are given in table AU.

TABLE AU.—SEPARATION FACTORS USED AT AGES<sup>1</sup> 1 TO 4

	1	2	3	4
Separation factor $f_0^x$	0.410	0.470	0.480	0.480

<sup>1</sup> Age denoted by z.

It will be noted that the values are given by age only, and are assumed independent of sex or race. As the values used by Glover were based on German

<sup>19</sup> This was resumed in the tabulation of infant deaths for 1943.<sup>20</sup> U. S. Bureau of the Census, *op. cit.*, p. 310.

## CALCULATION OF RATES OF MORTALITY

119

statistics of 1911 and prior years, their appropriateness for use in connection with recent data for the United States was tested before they were used for this purpose. A technical explanation of the test which was applied is given in section A of the appendix.<sup>21</sup>

#### Adjustment of mortality rates at ages 0 to 4 for the effect of migration

In the method previously described for obtaining rates of mortality at ages 0 to 4, it was assumed that the population under observation was not affected by migration during the period and at the ages considered, and that the deaths allocated to each annual cohort of births included all the deaths occurring in the cohort, and no deaths outside the cohort. Actually, it must be supposed that the deaths reported included some deaths of children born outside the continental limits of the United States, and failed to include some deaths of infants born in the United States who died outside. Some indication of the effect of immigration can be gained from the census tabulations of foreign-born population. The effect of emigration is more difficult to appraise, but is believed to have been negligible at the ages and during the period under consideration, and was therefore ignored. In other words, it was assumed that the native population under age 5 on the date of the census included all the survivors of births of the 5-year period ending on that date.

The method employed to allow for the effect of immigration involves certain concepts which make it necessary to refer briefly to the calculation of death rates at ages 5 and over. The central death rate is defined in terms of the life table as<sup>22</sup>

$$m_x = \frac{d_x}{L_x} \quad (21)$$

In other words, it is the number of deaths occurring during a year in the stationary life table population at age  $x$  last birthday, divided by the total number of persons at age  $x$  last birthday in the stationary population. When the life table covers a short period, such as 1 or 3 years, it is usually assumed that this is equal to the central death rate computed from the actual data; that is,

$$m_x = \frac{D_x}{n P_x} \quad (22)$$

where  $D_x$  denotes the number of deaths in the period of observation at age  $x$  last birthday,  $P_x$  denotes the population at age  $x$  last birthday at the middle of the period, and  $n$  denotes the number of years in the period. This assumption serves to bridge the gap between the actual population and the ideal life table population. Under this method, migration presents no difficulty if it can be assumed that the net migration has been uniformly spread over the period. For, in that event, the adjustment required in the number of

person-years of exposure to the risk of dying is  $n/2$  times the net migration, and since the population at the middle of the period has already been subjected to about half the net migration for the entire period (and is multiplied by  $n$  in the formula), the necessary adjustment is automatically taken care of.

This method of obtaining mortality rates was not used at the very young ages because of the known deficiency in the census enumeration. However, the procedure actually followed, while designed to produce estimated populations corrected for underenumeration, yields an estimate of the native population only (ignoring emigration). Now, formula (22) can be written in the form:

$$m_x = \frac{D_x}{n P_x} \cdot \frac{P_x^N}{P_x} = m_x^N \cdot \frac{P_x^N}{P_x}$$

when  $P_x^N$  denotes the native population at age  $x$  last birthday at the middle of the period, and  $m_x^N$  denotes an approximate value of  $m_x$ , in which the native population, rather than the total population, has been used as the denominator. Since the value of  $m_x$  obtained from births and deaths by the process described is really  $m_x^N$ , it needs to be corrected by multiplying by the factor  $P_x^N/P_x$ .

If it is assumed (as it usually is) that, in the life table,  $L_x = l_x - \frac{1}{2}d_x$ , it follows that<sup>23</sup>

$$m_x = \frac{2q_x}{2-q_x} \quad (23)$$

or, solving for  $q_x$ ,

$$q_x = \frac{2m_x}{2+m_x} \quad (24)$$

Therefore, it would be possible to convert the values of  $q_x$  obtained without considering migration into values of  $m_x$  by formula (23), multiply them by  $P_x^N/P_x$ , and then convert them back to  $q_x$  values by formula (24). However, this lengthy procedure is unnecessary, for the ratio  $P_x^N/P_x$  is always very close to unity, and thus represents only a slight adjustment; and putting equation (24) in the form:

$$\begin{aligned} q_x &= m_x \left( 1 + \frac{1}{2}m_x \right)^{-1} \\ &= m_x - \frac{1}{2}m_x^2 + \dots \end{aligned}$$

shows that a slight adjustment in the value of  $m_x$  results in a very nearly proportional adjustment in  $q_x$ . Therefore, the adjustment factor  $P_x^N/P_x$  may, without appreciable error, be applied to the values of  $q_x$  directly.

In the case of the life tables in this volume,  $P_x^N$  and  $P_x$  should properly represent populations on July 1, 1940, the midpoint of the 3-year period 1939-1941. However, since the adjustment involved is small in any case, it

<sup>21</sup> See p. 135.

<sup>22</sup> See pp. 21-22 for definition and explanation of the life table functions.

<sup>23</sup> Spurgeon, E. F., *Life Contingencies*, third edition, pp. 4-5, Cambridge University Press, London, 1938.

120

## UNITED STATES LIFE TABLES AND ACTUARIAL TABLES

was felt that little error would result in calculating this ratio from populations on the census date (April 1, 1940). Hence, the actual procedure at ages 1 to 4, was merely to multiply the unadjusted rate of mortality by the ratio of the native population to the total population, as enumerated in the census, at the corresponding age and in the same classification by race and sex. This, of course, involves the assumption that the enumeration was equally complete for the native and foreign-born elements of the population. The method used in estimating the distribution of the foreign-born under age 5 by single years of age has already been described,<sup>24</sup> and the resulting distribution by nativity, race, and sex of the population on April 1, 1940, is given in part I of table AM.<sup>25</sup>

The above method is not appropriate for adjusting the mortality rate at age 0, because in that case, the small amount of immigration which occurs is believed to be heavily concentrated in the latter part of the year of life, while the mortality is very much heavier in the early part. Therefore, the application of the ratio  $P_0^N/P_0$  to the mortality rate  $q_0$  would greatly overstate the amount of the necessary correction. Hence, the expedient was adopted of applying the adjustment ratio to the mortality rate for the second portion only of the first year of life; that is, to the probability  ${}_1q_0 = 1 - {}_1p_0$ .

The numerical illustration showing the calculation of mortality rates for white males in the United States in 1939–1941 is completed, for ages 1 to 4, in table AW which exhibits the adjustment for the effect of migration.

TABLE AW.—ADJUSTMENT OF RATES OF MORTALITY FOR WHITE MALES AT AGES<sup>1</sup> 1 TO 4, TO ALLOW FOR IMMIGRATION: UNITED STATES, 1939–1941

<sup>1</sup> Age denoted by  $x$ .

<sup>2</sup> Estimated native white male population at age  $x$  divided by total white male population at age  $x$ , April 1, 1940. See table AM, part I, p. 113.

In the case of age 0, formulas (16) and (17) give  ${}_1p_0 = .96029016$  and  ${}_1q_0 = .99124082$ . It follows that  ${}_1q_0$ , the complement of  ${}_1p_0$ , is .00875918. Multiplying this value by the adjustment factor .99973095, which is the quotient of the number of native white males enumerated at age 0 by the total white males so enumerated, gives .00875682 as the corrected value of  ${}_1q_0$ . The complement  ${}_1p_0$ , which is .99124318, multiplied by  ${}_1q_0$  gives .9518811 as the adjusted value of  $p_0$ . The complement .0481189 is the final value of  $q_0$ .

There is a criticism of the theory underlying the method adopted in correcting for the effect of migration in the mortality rates at ages under 5, in that the deaths which were deducted from the recorded births in order to obtain the number of survivors at the var-

ious ages include some deaths of children born outside the United States, so that the number of survivors of the native births is understated. As the deaths improperly deducted are very few, the resulting error is slight, and in any case serves as a partial offset to the failure to take account of emigration.

#### Grouping of ages for the computation of rates of mortality at ages 5 and over

Deaths at ages 5 and over were not tabulated by single years of age during the period 1939–1941, but only in the 5-year age groups 5–9, 10–14, etc., with a final group at ages 100 and over. As a matter of fact, it has frequently been considered preferable, in the construction of national life tables, to work with grouped data for the reason that statements of age, both in death reports and in the census, usually show what is known as "heaping": that is, marked preference for ages ending in certain digits, at the expense of other digits. This preference is especially noticeable in the case of ages which are multiples of five; while, to a lesser degree, even numbers tend to be given more frequently than odd numbers. A notable exception to the latter rule is observed at age 21, where a marked concentration is commonly found. The use of grouped data tends to smooth out the irregularities resulting from digit preference by averaging together ages at which the reported figures are excessive and other ages where a deficiency appears.

However, the particular grouping in which the 1939–1941 deaths were tabulated has not often been found the most satisfactory from the point of view of life table construction.<sup>26</sup> Glover had both deaths and populations tabulated by single years of age, and made an exhaustive study<sup>27</sup> of the results of all the possible methods of grouping in 5-year periods, finally deciding on the grouping 4–8, 9–13, etc. Wolfenden<sup>28</sup> has also given a very full discussion of the general problem of heaping and the conclusions reached by a number of actuaries as to the best method of age grouping for the data of various countries. In dealing with the 1939–1941 data, there was, however, no choice as to the mode of grouping, insofar as deaths are concerned. While the census populations were available by single years of age, the estimated populations on July 1, 1940, were much more easily obtained for the age groups in which deaths were available, and the computation of rates of mortality is appreciably simplified by having deaths and populations similarly grouped.

Nevertheless, it was thought advisable to study the nature of the heaping present in the population data of the 1940 census and to test the effect of various

<sup>24</sup> See, however, Nathan Keyfitz, *Census Monograph No. 18, Canadian Life Tables, 1931*, p. 8, Dominion Bureau of Statistics, Ottawa, 1937. Here, the "5–9" grouping was decided upon, even though both populations and deaths were available by single years of age.

## CALCULATION OF RATES OF MORTALITY

121

possible groupings. This was done by summing the reported figures for ages ending with the same digit and comparing the totals by means of Myers' "blended" method.<sup>20</sup> For comparison, the deaths of the year 1935, the most recent year for which deaths have been tabulated by single years of age, were analyzed in the same way. In this method of analysis, the ages below 20 are omitted, because they exhibit a pattern of digit preference which differs markedly from that observed at adult ages. The ages in the immediate neighborhood of age 21 may also be omitted because of the peculiar form of heaping usually present there.<sup>21</sup> Myers' blended method is designed to eliminate any bias due to a particular choice of the starting age.

In this case, ages 23 to 32 were employed as starting ages and the summations were not carried beyond age 99.<sup>22</sup> The results are shown in table AY. In this table, Negroes and other races are not shown separately, because these separate races were not tabulated by single years of age in the 1940 census. In interpreting the table, it should be noted that the extent of heaping or deficiency at any particular digit is indicated by the amount by which the percent shown for that digit differs from 10 percent. The "index of preference," which is the sum of the absolute deviations from 10 percent, is a useful general measure of the amount of bias present. The smaller the index, the less error is present, since if there were no bias, all the percentages would be exactly 10 percent, and the index would be 0.

TABLE AY.—PREFERENCE FOR DIGITS OF AGE BY RACE AND SEX, IN THE UNITED STATES, FOR 1935 DEATHS AND 1940 CENSUS POPULATIONS: NUMBERS REPORTED AT EACH DIGIT OF AGE<sup>1</sup> AS PERCENT OF TOTAL NUMBER

DIGIT OF AGE	1935 DEATHS				1940 POPULATIONS					
	Total deaths	White		Nonwhite		White		Nonwhite		
		Male	Female	Male	Female	Male	Female	Male		
		Total population								
0.	11.1	10.5	10.6	15.8	15.9	11.6	11.0	11.5	14.6	15.0
1.	8.7	9.0	8.9	7.4	7.3	8.5	8.8	8.6	6.8	6.5
2.	10.0	10.0	10.0	9.8	9.6	10.4	10.5	10.4	10.1	9.9
3.	9.7	9.9	9.8	8.4	8.4	9.6	9.8	9.6	8.3	8.2
4.	10.1	10.2	10.3	8.9	9.1	9.7	9.9	9.8	9.0	8.8
5.	11.4	11.0	10.9	14.5	14.1	10.7	10.5	10.6	12.5	12.4
6.	9.6	9.7	9.8	8.4	8.6	9.6	9.7	9.7	9.0	9.0
7.	9.6	9.8	9.7	8.2	8.4	9.6	9.7	9.6	8.8	8.7
8.	10.1	10.1	10.1	9.7	9.7	10.3	10.1	10.3	10.6	11.2
9.	9.7	9.8	9.9	8.9	8.9	10.0	10.0	9.9	10.3	10.5
Index of preference <sup>2</sup>	5.4	3.6	3.8	20.6	20.0	6.0	4.2	5.6	16.2	18.2

<sup>1</sup> Computed by Myers' blended method, using starting ages 23 to 32 and ending at age 99 in all cases.

<sup>2</sup> Sum of deviations from 10 percent, taken without regard to sign.

Inspection of the values of the index of preference shows, as might be expected, that the error is much more serious for the nonwhite than for the white races. Among white persons, there is slightly greater bias

<sup>20</sup> Myers, Robert J., *Errors and Bias in the Reporting of Ages in Census Data*, Transactions, Actuarial Society of America, vol. 41, Part 2, No. 101, pp. 386-415, October-November 1940. See especially pp. 402-407, 411-415.

<sup>21</sup> See p. 120.

<sup>22</sup> For the details of Myers' method, see his article, previously cited.

in the populations than in the death statistics; but among the nonwhite the reverse is true. In fact, in the nonwhite deaths, the heaping on digits 0 and 5 is so pronounced that all the other digits show a deficiency. Table AZ shows the value of the index of preference for the total population in each census from 1880 to 1940. With the exception of the 1940 figure, these values are taken from Myers' article.<sup>23</sup> This table indicates a steady improvement over the entire period in the accuracy of age statements. The relatively low figure for 1900 is due to the fact that in that census both age and date of birth were asked for, while in other censuses only age was obtained.

TABLE AZ.—INDEX OF PREFERENCE IN STATEMENTS OF AGE IN THE CENSUS OF POPULATION: UNITED STATES, 1880-1940

CENSUS	Index of preference	CENSUS	Index of preference
1880	20.8	1920	9.0
1890	15.6	1930	8.6
1900	9.4	1940	6.0
1910	11.2		

The percents in table AY may be used to test the effectiveness of different grouping methods by adding the percentages for the five digits which are combined in the particular grouping method. The closer the resulting total is to 50 percent, the better is the given method. Table BA shows the results obtained with the data of table AY. If it can be assumed that the pattern of digit preference among the 1939-1941 deaths was similar to that found in 1935, evaluation of table BA purely on the basis of the proximity of the totals to 50 percent would indicate the best groupings for deaths to be "1-5" for whites and "2-6" for nonwhites; while for the populations the preferred groupings would be either "4-8" or "5-9" for whites and "4-8" for nonwhites. However, in computing rates of mortality, if the same grouping is to be used for both populations and deaths, it is of little avail to select the most effective grouping for populations if this grouping produces marked bias in the death figures, and vice versa. On the other hand, the correct mortality rates will be obtained, even with considerable error in both population and death statistics, if both are deficient or both excessive in the same proportion. This suggests choosing as the best age grouping for mortality rate calculations the one in which the smallest difference is found between the percents in table BA for deaths and populations. This criterion indicates as the best groupings "5-9" for whites and "4-8" for nonwhites. Since the "5-9" grouping appears to be an advantageous one for the data of white lives, and no other grouping is actually available in the census for Negroes and other races separately, and in view of the simplification which results from employing the same grouping for both populations and deaths, it was decided to use the "5-9" grouping throughout.

## UNITED STATES LIFE TABLES AND ACTUARIAL TABLES

TABLE BA.—PERCENTAGE OF TOTAL REPORTED IN VARIOUS QUINQUENNIAL AGE GROUPINGS IN THE UNITED STATES, FOR 1935 DEATHS AND 1940 CENSUS POPULATIONS<sup>1</sup>

DIGIT GROUPING	1935 DEATHS				1940 POPULATIONS					
	Total deaths	White		Nonwhite		Total population	White		Nonwhite	
		Male	Female	Male	Female		Male	Female	Male	Female
1-5-----	49.9	50.1	49.9	49.0	48.5	48.9	49.5	49.0	46.7	45.6
2-6-----	50.8	50.8	50.8	50.0	49.8	50.0	50.4	50.1	48.9	48.3
3-7-----	50.4	50.6	50.5	48.4	48.6	49.2	49.6	49.3	47.6	47.1
4-8-----	50.8	50.8	50.8	49.7	49.9	49.0	49.9	50.0	49.9	50.1
5-9-----	50.4	50.4	50.4	49.7	49.7	50.2	50.0	50.1	51.2	51.8

<sup>1</sup> The figures in this table were obtained by summing the appropriate ones in table A.V.

#### General procedure used in obtaining rates of mortality at ages 5 and over

The method used in obtaining mortality rates for individual years at age from the grouped data at ages 5 and over was that of osculatory interpolation. This method has been used for many years in the construction of the national life tables of England and Wales, and the United States, and was adopted in the most recent official life tables of Canada and Australia. It produces a satisfactory degree of smoothness while at the same time yielding mortality rates which fit the original data closely. Osculatory interpolation may be defined as that method of interpolation which insures smooth junction between the curves representing the interpolated values in adjacent tabular intervals by requiring that such adjacent curves have the same first derivative (or, sometimes, the same first and second derivatives) at the point of junction.<sup>33</sup>

In applying the principle of osculatory interpolation to the construction of life tables, there are two possible methods of approach. In the first method, osculatory interpolation is applied to the populations and deaths separately in order to obtain smooth interpolated values for single years of age. The rates of mortality are then computed by relating the interpolated values for deaths and population at each age. In the second method, "pivotal" rates of mortality are obtained at specified intervals, and osculatory interpolation is then applied directly to the mortality rates, in order to fill in the intermediate values. The pivotal rates are obtained by first deriving pivotal values of populations and deaths separately from quinquennial (or other) sums of data, usually by ordinary interpolation, the interpolation process being sometimes combined with a certain amount of graduation, or smoothing.

There has been much discussion of the relative merits of these two methods of approach. The first method was introduced by Dr. John Tatham and used by him in constructing the English Life table number 6, covering the period 1891-1900. It was improved by George King, and in this improved form was adopted in this

country by Glover and Foudray and has been used in all previous United States life tables. The second method was introduced by George King in connection with the English Life tables numbers 7 and 8, and has been followed by Sir Alfred Watson in preparing the subsequent tables numbers 9 and 10. It has also been used in the most recent official life tables for Canada and Australia. For the former method it is argued that by its use the investigator is enabled to keep closer to the original data, and can test the reasonableness of the interpolated results in the light of his knowledge of the basic characteristics of the populations he is dealing with. The method also has the practical advantages that it requires no decision as to the ages at which pivotal values are to be calculated or the formula to be used in obtaining them, and that mortality rates for any combination of the original population classes can be readily obtained without performing a new interpolation. Such a case, for example, would be the preparation of a life table for total whites, after separate tables for white males and white females had been completed.

For the second method it may be argued that all mathematical formulas of interpolation, particularly those of the osculatory variety, are based on the assumption that the values being estimated can properly be expected to form a smooth series. Now, it can reasonably be expected that, with a large enough body of data, the rates of mortality should exhibit a smooth progression from age to age. However, the populations and deaths at single ages, arising as they do from fluctuating annual cohorts of births, and affected to a considerable extent by the incidence of past migration, can hardly be expected to be perfectly smooth. Hence, the assumption underlying the use of an interpolation formula is not entirely valid when it is applied to such data. There is also a practical advantage in that only one complete interpolation is required, as against the two separate interpolations needed in the other method. Also, the second method is found, in general, to produce a smoother series, because the graduating effect of the osculatory formula is applied directly to the mortality rates. A further point is made by Sir George Hardy, who states<sup>34</sup> that in "graduating separately the numbers in the two series of 'exposed to risk' and 'died' rather than their ratio, . . . we thereby discard our previous knowledge of the nature of the curve expressing that ratio—our general knowledge, that is, of the nature of the curve  $q_x$  or  $\mu_x$ ."

In the preparation of the present life tables, careful consideration was given to the choice as between the two general methods of procedure, and experimental calculations were made by both methods. In the end, the method of operating directly on the rates of mortality was adopted, as it was found to produce smoother

<sup>33</sup> For a synopsis of the theory of osculatory interpolation and of the historical development of the subject, see Hugh H. Wolfenden, *The Fundamental Principles of Mathematical Statistics*, pp. 121-132, Actuarial Society of America, New York, 1942.

## CALCULATION OF RATES OF MORTALITY

values, and the theoretical arguments in its favor seemed more cogent. Pivotal values of both populations and deaths were obtained by interpolation for the middle age of each of the age groups used: that is, at ages 7, 12, 17, etc., and the corresponding pivotal rates of mortality were obtained by the usual formula:

$$q_x = \frac{D_x}{nP_x + \frac{1}{n}D_x} \quad (25)$$

where  $D_x$  and  $P_x$  denote the pivotal values of deaths and populations, respectively, and  $n$  is the number of years in the period of observation: in this instance, 3. This formula is obtained at once by substituting in formula (24) the value of  $m_x$  given by formula (22). On the basis of these pivotal rates, values of  $g_x$  were obtained by osculatory interpolation for all integral ages from age 5 to the limiting age of each life table. The formulas used in obtaining pivotal values and in performing the osculatory interpolation, the method of securing smooth junction with the mortality rates at ages under 5, and the special devices adopted to extend the tables into the very high ages where the use of actual data leads to unreasonable results, are described in the sections which follow.

#### Pivotal value formulas employed

The pivotal value formula employed in the majority of cases was the usual King formula, which, written in central difference notation, is:<sup>35</sup>

$$v_x = .2w_x - .008\delta^2 w_x \quad (26)$$

where  $v_x$  denotes an interpolated value for the single year of age  $x$ ;  $w_x$  denotes a quinquennial sum of data centered on age  $x$ : in other words,  $w_x = \sum_{t=-2}^2 u_{x+t}$ , where the "u's" denote unadjusted single year values; and the symbol  $\delta$  denotes a central difference<sup>36</sup> taken at quinquennial intervals. In other words, if data (e. g., deaths or populations) are available for three consecutive 5-year age groups, this is a formula for estimating the number at the single age in the middle of the middle group. If the single year values for all 15 ages are exactly fitted by a third degree polynomial, this formula gives exactly the correct value. The assumption is, therefore, that the single year values would be approximately fitted by a third degree polynomial if they were unaffected by age heaping or sampling error. To facilitate the numerical computation, the formula was put in the alternative form:

$$v_x = -.008w_{x-5} + .216w_x - .008w_{x+5} \quad (27)$$

which was used (with certain exceptions to be noted later) to compute pivotal values of populations and deaths at each fifth age from age 12 to 97. The pivotal

values for populations were taken to the nearest integer; those for deaths, to two places of decimals. In applying formula (27) to obtain pivotal values at age 97, figures for the age group 100 and over were used as though they represented the age group 100-104.

Applying King's formula to obtain a pivotal value at age 7 would involve substituting in the formula a value of  $w_2$ , which would be a sum of data for the age group 0-4. It was not considered proper to regard such a figure as belonging to the same series with the other " $w$ " values: in the case of the deaths, because of the special mortality conditions prevailing in the first year of life; and in the case of the populations, because of the substantial underenumeration of infants and small children in the census. Hence, the pivotal values at age 7 were obtained by the following special formula based on ordinary interpolation from sums of data for the three age groups 3-4, 5-9, and 10-14, assuming that the 12 single year values can be fitted by a second degree curve:

$$v_7 = \frac{1}{700} \left[ -25(u_3 + u_4) + 157w_7 - 7w_{12} \right] \quad (28)$$

To derive this formula, suppose that  $u_{7+x} = a + bx + cx^2$ . Then,

$$\begin{aligned} u_7 &= a \\ w_7 &= 5a + 10c \\ w_{12} &= 5a + 25b + 135c \\ u_3 + u_4 &= 2a - 7b + 25c \end{aligned}$$

Now if it be assumed that  $u_7 = m(u_3 + u_4) + nw_7 + rw_{12}$ , substituting the above expressions and equating coefficients of  $a$ ,  $b$ , and  $c$  gives:

$$\begin{aligned} 2m + 5n + 5r &= 1 \\ -7m + 25r &= 0 \\ 25m + 10n + 135r &= 0 \end{aligned}$$

Solving these equations yields  $m = -\frac{1}{28}$ ,  $n = \frac{157}{700}$ , and  $r = -\frac{1}{100}$ , which are precisely the coefficients in formula (28).

The other exceptions made to the use of King's pivotal value formula were confined to the life tables for Negroes and other races. In working with Negro data it has often been found that the substantial amount of heaping present tends to produce cyclical fluctuations or waves which give to certain portions of the graph of the  $q_x$  function somewhat the appearance of a sine curve superimposed on the basic mortality curve. This condition is quite apparent in the published graphs of the  $q_x$  function in certain previous United States life tables.<sup>37</sup> However, this peculiarity can scarcely be considered a genuine characteristic of the data and there would seem to be little justification for reproducing it in the life table.

It will be remembered that in the discussion of digit preference in age statements<sup>38</sup> the "5-9" grouping was found to be not the most desirable for the nonwhite

<sup>35</sup> For a derivation of King's formula, see pp. 109-110 of Wolfenden's *Actuarial Study*, previously cited.

<sup>38</sup> See p. 121.

## UNITED STATES LIFE TABLES AND ACTUARIAL TABLES

data. In fact, table BA shows that in the digit grouping 5-9, the nonwhite populations are overstated, while the nonwhite deaths are understated. In the digit grouping 0-4, the reverse would of course be true. This would mean that the rate of mortality would be consistently understated in the groups consisting of ages ending with the digits 5-9, and consistently overstated in the "0-4" groups, producing just the sine curve effect so frequently observed. When pivotal values were obtained by King's formula, this tendency was clearly observed from age 30 to about age 60, where it became obscured by more serious errors in age statement.<sup>39</sup> Although the osculatory interpolation formula used has a moderate graduating effect, this was found not to eliminate the waviness entirely. Therefore, it was decided to use also a pivotal value formula which incorporates an element of graduation.

The formula selected for this purpose was<sup>40</sup>

$$v_x = \frac{1}{7} [ .696w_x + .488(w_{x+5} + w_{x-5}) - .136(w_{x+10} + w_{x-10}) ] \quad (29)$$

This formula gives the middle term of a 25-term series summed in five groups of five, on the assumption that the individual terms can be represented by a third degree curve. However, it is not unique in this respect, as an infinite number of other formulas exist which have the same property. Its uniqueness lies in the fact that, of the entire class of such formulas, this is the one for which the mean square error of the interpolated value,  $v_x$ , is least, on the assumption that the mean square errors of the five sums of "u" values are all equal.<sup>41</sup>

This formula involves the assumption that the "true values," after adjusting for errors in the data, of any five consecutive age groups will be exactly fitted by a third degree curve. There are certain portions of the mortality curve in which this assumption is unsuitable. For both Negroes and "other races," this is true of the ages under 30, where the death statistics form a curve with very rapidly changing curvature, and where, in any case, the tendency to "waviness" is not apparent. Here the use of formula (29) was found to produce unwarranted distortion in the mortality rate; accordingly, King's formula was used. For the Negroes, a similar situation exists beyond age 75, where both populations and deaths are decreasing so rapidly that the assumption of fitting a third degree curve to the data of five consecutive age groups was clearly inappropriate. In the case of the data for "other races," populations and deaths also decrease rapidly above age 75, but the figures are so irregular, because of the small size of the data, that the smoothing effect of the special formula (29) was needed, and the values are so rough, in any case, that any distortion resulting from the use of this

formula is not of much importance. To sum up, formula (29) was used instead of King's formula in obtaining pivotal values of populations and deaths at ages 32 to 72, inclusive, for Negroes; and at ages 32 to 87, inclusive, for "other races."

## Derivation of pivotal rates of mortality

Pivotal rates of mortality were computed at every fifth age from age 7 to age 97 by applying formula (25) to the pivotal values of populations and deaths. They were carried out to seven decimal places on a unit basis: that is, to four decimal places on a per 1,000 basis. The progression of these rates at the very high ages was carefully studied, and unsuitable values were rejected by inspection. In the end, the originally calculated rates were retained through age 92 for white males and females and Negro males, and through age 87 for Negro females and "other races" males and females. In the case of the life tables for combinations of classes, pivotal rates of mortality were obtained by summing separately the values used as numerators and denominators in obtaining pivotal rates for the individual classes, at all ages at which the originally calculated rates were retained for all the individual classes included.

## Treatment of the very old ages

At the very old ages (those above age 90, approximately) mortality rates obtained in the conventional manner from the data as reported frequently appear unreasonable or even absurd. This condition is probably due in part to inaccuracies in age statements, and in part to random irregularities made possible by the very small size of the experience at these ages. It is customary, therefore, to reject those values which are considered unsuitable, and to end the life table in some more or less artificial manner. From a practical standpoint, it probably makes little difference what method is used for this purpose, as little reliance is placed on the values obtained at the very old ages, and they affect only slightly other life table values which are extensively used. The question may properly be raised as to why it is necessary to show life table values at all beyond those ages at which they can be considered reliable. It may be answered that, in order to obtain values of the average future lifetime and of life annuity and assurance premiums, it is necessary to assume *some* values of the rate of mortality at the oldest ages, and the user of the tables may properly wish to be informed as to what values were assumed.

In connection with the life tables included in this volume, the use of a fifth difference interpolation formula (as described in the next subsection) made it desirable to extend the series of pivotal rates of mortality in some manner, prior to performing the interpolation. This was done, in each case, by fitting a third degree curve to the last four pivotal rates retained. In carrying out the actual arithmetic, each pivotal rate

<sup>39</sup> See p. 110.

<sup>40</sup> This formula was first published in an unsigned book review in the Journal of the Institute of Actuaries, vol. 51, No. 272, p. 308, October 1919. It is also given by Wolfenden in his *Actuarial Study* (previously cited), p. 113.

<sup>41</sup> See Wolfenden's derivation of this formula, already referred to.

## CALCULATION OF RATES OF MORTALITY

beyond those retained from the original series was computed from the four preceding ones by the formula:

$$u_x = 4u_{x-5} - 6u_{x-10} + 4u_{x-15} - u_{x-20}$$

In the case of the life tables for combinations of classes, pivotal rates of mortality were not calculated beyond age 92. A special problem arose at age 92 when individual classes for which the originally calculated rate had been rejected were included in the combination. In such cases the pivotal value of the number of deaths, as originally calculated, was regarded as the correct numerator, and an adjusted denominator was obtained by dividing this numerator by the extrapolated pivotal rate of mortality. These adjusted denominators were carried out to two decimal places in order to avoid inconsistency between the life tables for combinations of classes and those for the individual classes included.

## Osculatory interpolation formulas used

The osculatory interpolation formula used for the main body of the life tables in this volume was Jenkins' modified fifth difference formula.<sup>42</sup> The word "modified" in the name of this formula indicates that, although satisfying the conditions of smooth junction, it does not exactly reproduce the pivotal rates of mortality, but has a moderate graduating effect. The advantages of using a formula of this type have been aptly expressed by the Scottish actuary, James Buchanan, who says:<sup>43</sup>

The weak point of the osculatory method, regarded as a smoothing agent, rests on the fact that the graduated curve is required to pass through certain predetermined points. The curve will in fact be constrained to take a form similar to that assumed by a flexible steel wire which is clamped at fixed points, so that, while the curve is free from discontinuities, any departure of these points from the smooth curve will be reproduced with resulting undulations. To remove this tendency to waviness, Jenkins has devised his modified osculatory method, which, while requiring the successive interpolation curves to have the same slope and curvature at their common points at the end of each interval, does not require the curves to pass through the points corresponding to the calculated values.

The practice of employing such a formula in the construction of national life tables has been slow to gain general acceptance, perhaps because it has been considered that fidelity to the original data is here more fundamental than smoothness. However, experience has shown that a well chosen modified osculatory formula can usually be depended on to preserve the basic underlying trend of the mortality curve, only local irregularities being smoothed out. National life tables are being increasingly used for population projections, valuation of old-age pensions and survivors' benefits,

and other calculations in which a lack of smoothness in the life table is likely to produce irregularities and inconsistencies which, although minor, can be awkward and inconvenient. Also, it may justly be argued that it is better to produce a smooth table which, in all likelihood, represents the true underlying conditions as precisely as they can be inferred from a careful analysis of the data, rather than a table which merely reproduces the data along with all the errors they are known to contain. It is a virtue of the better modified osculatory formulas that when applied to a series containing many undulations, such as rates of mortality for Negroes in the United States, they exert a considerable smoothing effect, and yet when applied to a series which is already fairly smooth, such as the corresponding rates for white persons, they produce only an insignificant change.

In the case of 5-year age intervals, Jenkins' modified fifth difference formula can be written in the form:<sup>44</sup>

$$v_{a+5} = \frac{s}{5} \left( u_a - \frac{1}{36} \delta^4 u_a \right) + \frac{s(s^2-25)}{750} \left( \delta^2 u_a - \frac{1}{6} \delta^4 u_a \right) + \\ \frac{t}{5} \left( u_{a+5} - \frac{1}{36} \delta^4 u_{a+5} \right) + \frac{t(t^2-25)}{750} \left( \delta^2 u_{a+5} - \frac{1}{6} \delta^4 u_{a+5} \right) \quad (30)$$

where  $u_a$  and  $u_{a+5}$  denote consecutive pivotal values,  $\delta$  denotes a central difference as before,  $t$  is a number between 0 and 5,  $s=5-t$ , and  $v_{a+5}$  denotes the interpolated value obtained by the formula. This formula produces contact of the second order: that is, the interpolation curves in any two adjacent age intervals have equal ordinates and equal first and second derivatives at their point of junction. It may be noted that this formula gives, on substituting  $t=0$  and 5, respectively:

$$v_a = u_a - \frac{1}{36} \delta^4 u_a \quad (31)$$

$$v_{a+5} = u_{a+5} - \frac{1}{36} \delta^4 u_{a+5} \quad (32)$$

These results show that the pivotal values are adjusted by the formula to the extent of 1/36 of the negative of the corresponding fourth central difference. Substituting the expressions (31) and (32) and writing  $\delta^2 y_a$  for  $\delta^2 u_a - \frac{1}{6} \delta^4 u_a$  the equation (30) becomes:

$$v_{a+5} = \frac{s}{5} v_a + \frac{s(s^2-25)}{750} \delta^2 y_a + \frac{t}{5} v_{a+5} + \frac{t(t^2-25)}{750} \delta^2 y_{a+5} \quad (33)$$

In using a formula which appears in this symmetrical form, the arithmetic can be considerably shortened by

<sup>42</sup> Jenkins, W. A., *Graduation Based on a Modification of Osculatory Interpolation*. Transactions, Actuarial Society of America, vol. 28, Part 2, No. 78, p. 202, October 1927. The formula is also given (in a form more closely resembling that employed in this volume) by Robert Henderson, *Mathematical Theory of Graduation* (*Actuarial Studies No. 4*), second edition, p. 22, Actuarial Society of America, New York, 1938.

<sup>43</sup> Buchanan, James, *Recent Developments of Osculatory Interpolation, With Applications to the Construction of National and Other Life Tables*, Transactions of the Faculty of Actuaries (Scotland), vol. 12, Part 5, No. III, pp. 117-160, 1929.

<sup>44</sup> The form given here differs from that given by Jenkins and Henderson for the reason that here the single year of age is taken as the unit of reckoning, while in the other formulations the unit is the entire interval of interpolation (in this instance, 5 years). The formula given here is readily obtained from Henderson's expression upon replacing  $x$  by  $t/5$  and  $y$  by  $u/5$ . Jenkins' original statement of the formula was in terms of advancing differences rather than central differences.

126

## UNITED STATES LIFE TABLES AND ACTUARIAL TABLES

employing a special computation process in which the results of certain calculations are used twice.<sup>46</sup>

In the construction of all the life tables in this volume, this formula was used for interpolation from age 32 to the end of the table. As stated in the preceding subsection, the series of pivotal rates of mortality was extended to the very old ages by fitting a third degree curve to the last four of the original pivotal rates actually used, which is, of course, equivalent to assuming fourth differences to be 0. Under these conditions, formula (30) reduces to:

$$v_{a+t} = \frac{s}{5}u_a + \frac{s(s-25)}{750}\delta^2u_a + \frac{t}{5}u_{a+5} + \frac{t(t-25)}{750}\delta^2u_{a+5}$$

which is merely the ordinary Everett interpolation formula<sup>47</sup> for quinquennial intervals. This shows the special convenience, in connection with Jenkins' modified fifth difference formula, of the particular method chosen for terminating the life tables. It may be noted that, in carrying out the extrapolation for the very old ages, the second differences  $\delta^2u_a$  were values of a first degree curve (or straight line), and could therefore be obtained by the formula:

$$\delta^2u_a = 2\delta^2u_{a-5} - \delta^2u_{a-10} \quad (34)$$

This formula holds at the last age for which the calculated pivotal rate was retained, and at subsequent ages.

In the case of the life tables for combinations of classes, it was found that interpolation of the rates of mortality beyond age 92 would, in some instances, give results inconsistent with the rates for the component classes. Therefore, in all these tables, the interpolation was terminated at that point, and mortality rates for subsequent ages were obtained from the  $I_x$  column of the life table, which was itself derived by a special process to be explained later. The value of  $\delta^2g_{x2}$  to substitute in the interpolation formula was obtained by equation (34). This, of course, implicitly assumes the existence of an extrapolated pivotal rate at age 97.

Because of the rapid change of curvature of the  $g_x$  curve at ages under 30, and the small size of the rate of mortality at these ages, the fourth differences of  $g_x$  are quite large in relation to the values of  $g_x$  itself, and an excessive adjustment is introduced by Jenkins' formula, which has the effect of replacing the pivotal values originally calculated by adjusted values obtained by formula (31), involving a fourth difference correction. Moreover, the mortality curve commonly displays genuine irregularities at these ages, which it is not desirable to remove by a smoothing process. Therefore, it seemed the wisest course to use a formula which

would reproduce the pivotal values. The formula selected was the familiar Karup-King formula,<sup>48</sup>

$$v_{a+t} = \frac{s}{5}u_a + \frac{s^2(s-5)}{250}\delta^2u_a + \frac{t}{5}u_{a+5} + \frac{t^2(t-5)}{250}\delta^2u_{a+5} \quad (35)$$

This formula was used for interpolation in all the life tables between ages 12 and 27.

Between ages 4 and 12 and between 27 and 32, special extensions were devised in order to secure smooth junction, in the one case with the mortality rates under age 5 specially computed from birth and death statistics, and in the other case with the rates above age 32 interpolated by Jenkins' formula. Inasmuch as both the two interpolation formulas are of the third degree, third degree curves were employed for the special extensions as well. The curve used for ages 5 to 11 was required to reproduce the calculated rates of mortality at ages 4, 7, and 12, and to have the same derivative at age 12 as the Karup-King curve used between ages 12 and 17. The curve used for ages 28 to 31 was required to have its ordinate and first derivative equal to those of the adjoining Karup-King curve at age 27 and to those of the adjoining Jenkins curve at age 32. In both cases, there are four conditions imposed, and this is enough to determine a third degree curve. In each case also, it was possible to regard the interpolation by the special curve as merely a further application of the Karup-King formula, by utilizing a suitable artificial extension of the series of pivotal values.<sup>49</sup>

Seven decimal places were retained throughout the interpolation process, and the resulting interpolated rates of mortality were rounded to six places. They are further rounded to five places (or two places on a per 1,000 basis) in the published tables.

## Test of the graduation of the rates of mortality

Tests were applied to the final rates of mortality in each of the six life tables for individual classes of the population to determine whether the graduation could be deemed satisfactory. It was not considered necessary to test separately the mortality rates for combinations of classes. In making such tests, there are two chief points to be considered: (1) conformity to the original data, and (2) smoothness. Conformity to the original data is usually tested by calculating, for each age group, the number of deaths expected on the basis

<sup>46</sup> Freeman, *op. cit.*, pp. 73-75. See also T. N. E. Greville's discussion in the Record, American Institute of Actuaries, vol. 32, Part 1, No. 65, pp. 86-87, June 1943. See also Louis J. Dublin and Alfred J. Lotka, *Length of Life*, pp. 338-339, The Ronald Press Co., New York, 1936.

<sup>47</sup> Freeman, *op. cit.*, p. 66. The form given here may be obtained from Freeman's expression by substituting central differences for advancing differences, changing the origin so that  $a$  corresponds to Freeman's "0," and replacing  $x$  by  $t/5$  and  $y$  by  $s/5$ .

<sup>48</sup> For a discussion of computation methods, see John Boyer, *Osculatory Interpolation in Practice*, Record, American Institute of Actuaries, vol. 31, Part 2, No. 64, pp. 337-338, October 1942. A method similar to that mentioned in connection with the Jenkins formula can also be employed.

<sup>49</sup> The formulas which were used for this purpose are derived in the appendix, p. 136.

## CALCULATION OF RATES OF MORTALITY

127

of the calculated rates of mortality, and comparing this with the number of deaths actually reported. This would seem to be a simple enough procedure, but, in dealing with grouped data, questions immediately arise as to the proper method of calculating the expected deaths. The traditional method consists in multiplying the population at each single age by the number of years in the period of exposure and by the value of  $m_x$  at that age, based on the life table. In the present case, however, the populations used were estimated populations on July 1, 1940, and were not obtained by single years of age. Nor could such values be made available without considerable additional work, and without making some assumption as to the distribution of deaths by single ages. As an approximation to this procedure, experiments were made with the expedient of distributing the population in each 5-year age group into single years of age in the same proportion as the corresponding population on April 1, 1940, the date of the census. In the case of white males and white females, this method gave numbers of expected deaths consistently smaller than the corresponding number of reported deaths, although the differences were extremely small in most cases. This condition resulted from the fact that the greatest "heaping" occurs at the ages ending with the digits 0 and 5, and in the "5-9" mode of grouping these ages are, in every case, the youngest ages of the 5-year age groups in which they fall, and therefore, in general, the ages having the lowest mortality rate in the group. This padding at ages where mortality rates are lower results in understatement of the expected deaths.

Another possible method of computing the expected deaths would be to compute, from the life table, an average central death rate for each 5-year period by the formula:

$$m_x = \frac{l_x - l_{x+5}}{T_x - T_{x+5}} \quad (36)$$

and to apply this rate to the total population in the age group, multiplying also, of course, by the number of years in the period of exposure. In the case of white males and white females, this method has a tendency to produce expected deaths which are consistently very slightly in excess of the actual deaths. This results from the assumption underlying the method: namely, that the proportionate distribution by single years within the 5-year age group is the same in the actual population as in the hypothetical life table population. This assumption is not exactly fulfilled, as the numbers decrease more rapidly with age in the actual population, because of the effect of past migration and of a steadily declining birth rate in past years.

The fact that the general tendency of the relation between reported and expected deaths is completely reversed by making only a slight change in the method of computation of the expected deaths is in itself evi-

dence that an excellent fit has been secured; and, by either method, the differences are in most cases small fractions of 1 percent of the numbers of deaths involved. However, it was felt that a more meaningful comparison would be obtained by estimating the populations at single years of age by an osculatory interpolation formula which preserves the 5-year totals. For this purpose, the Karup-King formula was used. In this connection the interpolation in the age group 5-9 was performed by a special extension by means of a curve having the property of reproducing the enumerated population in the age group 3-4. The resulting comparison is shown in table BB. No comparison is made for the ages under 5, where the methods used in deriving mortality rates should, at least in theory, produce exact agreement between actual and expected deaths.

In the case of Negroes and "other races," the differences between reported and expected deaths are larger, and the comparison shows about the same relationships, regardless of how the expected deaths are computed. The method used in the case of white lives seemed, however, entirely suitable, and was therefore adopted. Table BB shows, for both Negro males and Negro females, a very large excess of expected over reported deaths in the age group 65-69, which is offset only to a small extent by deficiencies in the neighboring age groups. This is because the expected deaths were computed on the basis of populations as actually reported, while the rates of mortality are based on a redistribution by age of the population and deaths between ages 55 and 70. This redistribution was made in the belief that a substantial number of persons actually between ages 55 and 65 had been reported at ages between 65 and 70. If this is true, the expected deaths for the entire 15-year age period would be greatly overstated, because the rates of mortality are much higher at the ages incorrectly given than at the true ages of the groups affected by this error. Table BC shows how the comparison would be altered if based on the redistributed populations and deaths, and indicates that the calculated rates of mortality conform satisfactorily to the redistributed data.

The traditional procedure for testing the smoothness of the graduation of a series of rates of mortality calls for examination of the third differences of the graduated rates. If these are reasonably small and change sign fairly often, the smoothness of the graduation is considered satisfactory. The sum of the absolute values of the third differences over some specified range of

ages is often taken as a criterion of smoothness. It is not, however, entirely clear why third differences, rather than differences of some other order, should always be used for this purpose; and in fact, there are strong arguments, at least from a theoretical standpoint, to support the view that the most appropriate order of differences to be so used depends on the characteristics of the particular data, and on the graduation formula employed. For example, in connection with the life tables in this volume, it can reasonably be argued that fourth differences are more suitable at ages 32 and above.

TABLE BC.—COMPARISON OF ASSUMED AND EXPECTED DEATHS FOR NEGROES AT AGES 50 TO 74, BASED ON REDISTRIBUTED POPULATIONS AND DEATHS: UNITED STATES, 1939–1941

Net total			+446			+737

<sup>1</sup> Redistributed by age as described on p. 111.

<sup>2</sup> Using the values in this table for ages 50 to 74.

The argument is based on the fact that the interpolation formula employed above age 32 (Jenkins' fifth difference modified formula) has the property of reproducing a third degree curve. In other words, if it should happen that the guiding values at quinquennial ages were exactly the values of some third degree polynomial for the corresponding ages, then all the interpolated values would also be the corresponding values of the same polynomial. This implies that when a third degree curve can be fitted to the guiding values, such a curve constitutes an entirely satisfactory graduation, and does not require adjustment. Now, the third differences of a third degree polynomial are constant; therefore, they need not be small, and obviously do not change sign. Thus, the conventional test for smoothness employing third differences is inconsistent with the philosophy underlying the interpolation formula used. On the other hand, the fourth differences of a third degree polynomial are 0, so that there is no inconsistency in testing for smoothness by an examination of fourth differences.

The interpolation formulas used at ages under 32 have the property of reproducing second degree polynomials only, so that the same line of reasoning would justify the application of a third-difference test for smoothness. Table BD gives both the third and fourth differences of the rates of mortality for each of the six single classes of the population for ages 4 to 87, in-

## CALCULATION OF RATES OF MORTALITY

129

clusive. The rates for ages under 5 were not graduated, but age 4 is included in the table because the value of  $q_4$  was used to secure smooth junction with the rates for subsequent ages. As the method used in extrapolating mortality rates at the old ages resulted in employing a single third degree curve for all ages above 87, the mortality rates at these ages do not need to be tested for smoothness.

The range of ages covered by the table has been divided into three intervals of 28 ages each, for which separate totals are shown in table BD. The first of these intervals, including ages 4 to 31, is precisely the area in which it was argued on theoretical grounds that a criterion of smoothness based on third differences is appropriate. In general, it appears that in the two

younger age intervals the differences of both orders change sign frequently, and the sum of the absolute values is satisfactorily small in both cases, being somewhat smaller for third differences than for fourth differences. However, in the oldest age interval, 60 to 87, the third differences show a marked tendency to form clusters of positive and negative values, and the sums of their absolute values are large, so that the graduation would probably be rejected as not sufficiently smooth if strict reliance were placed on third differences as the criterion of smoothness. On the other hand, the fourth differences in this interval change sign frequently and have small numerical values. Hence, on the basis of fourth differences, the smoothness would be judged satisfactory throughout.

## UNITED STATES LIFE TABLES AND ACTUARIAL TABLES

As regards the relative magnitude of third and fourth differences in the two younger age intervals, it should be pointed out that rounding errors contribute the greater part of the numerical values of differences at these ages, and their effect becomes more marked as the order of differences increases. This point is illustrated in table BE, which shows both the third and fourth differences obtained from the mortality rates for white males by retaining all the seven decimal places to which these rates were originally computed. Comparison of table BD and table BE shows that the absolute values of the differences are greatly reduced by using the two additional decimal places. (Note that figures in table BD must be multiplied by 100 to make them comparable with those of table BE.) The reduction in the sum of the absolute values over the

entire age range shown amounts to 23 percent in the case of third differences and 74 percent in the case of fourth differences. Table BE shows that, in each of the three age subdivisions, the sum of the absolute values is less for fourth than for third differences when the effect of rounding is eliminated. It also shows that the third differences are in reality predominantly positive and do not change sign at all frequently above age 30. Therefore, the mortality rates would not have been considered satisfactory above age 30 if third differences had been taken as the criterion. This seems to reinforce the suggestion made earlier that the order of differences to be employed for this purpose should be varied according to the characteristics of the basic data and the graduation procedure used.

## CALCULATION OF LIFE TABLE FUNCTIONS

133

## C. CALCULATION OF OTHER LIFE TABLE FUNCTIONS

Calculation of  $l_x$  and  $d_x$ 

The values of  $l_x$  and  $d_x$  were obtained by successive multiplication and subtraction commencing with a radix of 100,000 at birth, by the usual elementary formulas:

$$\begin{aligned} d_x &= l_x q_x \\ l_{x+1} &= l_x - d_x \end{aligned} \quad (37)$$

Values of  $q_x$  were used to seven decimal places, and three decimals were retained in the  $l_x$  and  $d_x$  values. At the very old ages, the number was increased, so as to give seven significant figures in every case. Although the published tables are terminated, in each case, at that age where  $l_x$ , taken to the nearest integer, first becomes 0, nevertheless, for reasons which will be explained later,<sup>49</sup> it was desired to have  $l_x$  values computed further for use in calculating the values of  $\bar{e}_x$ , the average future lifetime. Accordingly, the process was continued so long as  $l_x$  values in excess of .0025 were obtained.

In the life tables for combinations of classes, this process could be carried only to age 93, as interpolated rates of mortality were not obtained beyond age 92. These tables were completed by a special process designed to avoid inconsistencies between the  $q_x$  values for the combination and those for the component classes. The value of  $l_{92}$  in the combined table was divided into as many parts as there were separate classes included, the division being made in proportion to the denominators used in computing the pivotal values of  $q_{92}$  for the corresponding life tables. Each separate part of the  $l_{92}$  figures was then carried forward by applying the mortality rates for the corresponding separate class, the results being summed to obtain the subsequent  $l_x$  values for the combined table. This is equivalent to expressing the value of  $l_x$  for the combined table as a weighted sum of the  $l_x$  values from the separate life tables for the component parts. Using the latter process shortens the arithmetic. For example, let  $l_x^{(1)}$ ,  $l_x^{(2)}$ , etc., denote the  $l_x$  values in the separate life tables for the component classes, let  $l_{92}'$ ,  $l_{92}''$ , etc., denote the corresponding parts into which  $l_{92}$  for the combined table is divided, and let  $w_1 = l_{92}^{(1)}/l_{92}'$ ,  $w_2 = l_{92}^{(2)}/l_{92}''$ , etc. Then, at ages above 92,  $l_x$  for the combined table is given by

$$l_x = w_1 l_x^{(1)} + w_2 l_x^{(2)} + \dots$$

The  $q_x$  values were then obtained by the formula:

$$q_x = 1 - \frac{l_{x+1}}{l_x}$$

In the published tables, all the  $l_x$  values have been rounded to the nearest integer, while the published  $d_x$  values have been obtained by differencing the published

$l_x$  column, and, for that reason, differ slightly in some cases from the figures which would result from rounding the  $d_x$  values as originally calculated.

In view of the necessarily rough nature of the adjustments made in the data for subdivisions of the first year of life,<sup>50</sup> it was not felt that much refinement was justified in calculating the life table functions for these subdivisions. Accordingly, the value of  $d_0$  obtained for the main life table was merely divided among the various age periods within the first year in proportion to the numbers of deaths in each age period during the 3 years (after adjustment for underreporting, and smoothing of the "other races" data). The intermediate  $l_x$  values were then obtained by subtraction, and the mortality rates by division.

Calculation of  $L_x$ 

At ages 5 and over, it was considered sufficiently accurate to assume that

$$L_x = \frac{1}{2}(l_x + l_{x+1})$$

At ages 1 to 4,  $L_x$  was obtained by the formula:

$$L_x = l_x - (1 - f_x)d_x = l_{x+1} + f_x d_x$$

where  $f_x$  denotes the separation factor previously referred to.<sup>51</sup> In justification of this formula, it may be pointed out that, in the hypothetical stationary population,  $L_x$  represents the number of persons at age  $x$  last birthday who would be enumerated by a census taken at any time. Naturally this is equal to the number who have reached exact age  $x$  during the preceding year less those who have died in the meantime: that is,  $l_x$  less a part of  $d_x$ . If the incidence of deaths during a calendar year is the same in the stationary population as in the actual experience, the fraction of  $d_x$  to be taken is<sup>52</sup>  $D_x/D_x = 1 - f_x$ .

The value of  $L_0$  was obtained by making separate calculations for the various subdivisions of the first year of life and adding. The process used is most readily explained by adopting the point of view which considers  $L_0$  as the total number of person-years of life lived, between birth and exact age 1, by  $l_0$  infants born alive. The function  $T_x - T_{x+t}$  for a particular age interval,  $x$  to  $x+t$ , within the first year of life represents the number of person-years lived between these exact ages by the survivors of  $l_0$  live births. This would be given by

$$T_x - T_{x+t} = l_x - \frac{1}{2}t d_x = \frac{1}{2}t(l_x + l_{x+1}) \quad (38)$$

on the assumption that those who die between ages  $x$  and  $x+t$  live, on the average, half the period. It was necessary to express the values of  $t$  as fractions of a year,

<sup>49</sup> See p. 134.<sup>50</sup> See p. 108.<sup>51</sup> See p. 117.<sup>52</sup> See p. 115.

134

## UNITED STATES LIFE TABLES AND ACTUARIAL TABLES

on the same assumption previously made<sup>13</sup> that the total length of the year was 365½ days. The value of  $L_0$  was taken as the sum of the values of  $T_x - T_{x+t}$  for all subdivisions of the first year of life.

With the exception of  $L_0$ , all the values of  $L_x$  were retained to not less than one place of decimals and to not less than six significant figures, for use in subsequent calculations. Values of  $T_x - T_{x+t}$  for subdivisions of the first year of life were rounded to the nearest integer before addition. Values of  $L_x$  were obtained in each case up to, but not including the last age for which  $l_x$  was computed, but are shown in the published tables only when the value is at least 1 to the nearest integer. The published  $L_x$  values (except in the first year of life) were obtained by differencing the published  $T_x$  column, and therefore differ slightly in some cases from the figures which would result from rounding the originally calculated  $L_x$  values directly.

Calculation of  $T_x$  and  $e_x$ 

Values of  $T_x$  were obtained by accumulating the computed values of  $L_x$  from the oldest age available down to age 0. The values of  $T_x - T_{x+t}$  for subdivisions of the first year of life were added one by one, proceed-

<sup>13</sup> See p. 108.

ing backward from age 1, in order to obtain  $T_x$  values within the first year. In the calculation of  $e_x$  each value of  $T_x$  was used to the smallest number of decimal places retained in any of the  $L_x$  values included in it. However, the published values of  $T_x$  have all been rounded to the nearest integer.

The values of  $e_x$ , carried out to two decimal places in all cases, were computed by the formula:

$$e_x = \frac{T_x}{l_x}$$

the  $l_x$  values being used to the full number of decimal places originally retained. In order to obtain plausible values of  $e_x$  at the oldest ages shown in the published tables, the actual computation of  $l_x$  values was continued so long as the values obtained exceeded .0025. In arriving at this limit, it was reasoned that the ages for which figures appear in the tables are those for which  $l_x$  is at least 1 to the nearest integer: that is, the exact value is at least .5. Therefore, accuracy to two decimal places will be secured, in most cases, by using, in the computation of  $T_x$ , all values of  $l_x$  which, when divided by .5, give a quotient of at least ½ of .01, or .005: that is, all values of  $l_x$  in excess of .0025.

## APPENDIX

### A. METHOD USED IN TESTING THE APPROPRIATENESS OF GLOVER'S SEPARATION FACTORS

It was stated in part V<sup>1</sup> that in dividing the deaths  $D_x$  occurring in each calendar year at ages 1 to 4 into the two parts  $\cdot D_x$  and  $\cdot D_x$  according to the year of birth, it was necessary to employ the same separation factors  $f_x$  used by Glover in connection with the 1910 life tables, as no statistics were available on which a new determination could be based. However, the appropriateness of Glover's factors for use with the 1939-1941 data was first tested in the manner described below.

Let  $\theta_{x+t} dt$  denote the number of deaths which occur during a specified period of observation (assumed to be an integral number of years) between age  $x+t$  ( $x$  being an integer and  $t$  a fraction) and age  $x+t+dt$ , let  $D_x$  denote the total deaths during the period at age  $x$  last birthday, and let  $K_{x+t}$  denote the total deaths at all ages under  $x+t$ , so that  $K_x = \sum_{z=0}^{x-1} D_z$ . It follows immediately that

$$K_{x+t} = \int_0^{x+t} \theta_z dz$$

therefore,  $\frac{d}{dt} K_{x+t} = \theta_{x+t}$ . On the assumption that the  $\theta_{x+t} dt$  deaths occurring at exact age  $x+t$  are uniformly distributed over each of the calendar years covered, these would include  $t\theta_{x+t} dt$  deaths where exact age  $x$  was attained in the calendar year preceding the year of death, and  $(1-t)\theta_{x+t} dt$  deaths where exact age  $x$  was attained in the year of death. The total number of deaths in the calendar year following the attainment of exact age  $x$ , but before attaining age  $x+1$ , which may be denoted by  $\cdot D_x$ , would therefore be:

$$\int_0^1 t\theta_{x+t} dt$$

Considering this expression to be of the form  $\int U dV$ , where  $U=t$  and  $dV=\theta_{x+t} dt$ , and integrating by parts gives:

$$\cdot D_x = K_{x+1} - \int_0^1 K_{x+t} dt$$

Dividing by  $D_x$  gives an average separation factor for the entire period of observation, which may be represented by  $f_x$ . Thus,

$$f_x = \frac{1}{D_x} (K_{x+1} - \int_0^1 K_{x+t} dt) \quad (39)$$

Values of the expression (39) were obtained for ages 1, 2, and 3 by using the deaths of the 3-year period 1939-1941 and employing an approximate integration formula to evaluate the integral. In the case of ages 2 and 3, the formula used for this purpose was the symmetrical formula:

$$\int_0^1 K_{x+t} dt = \frac{1}{24} (-K_{x-1} + 13K_x + 13K_{x+1} - K_{x+2})$$

which is obtained by fitting a third degree polynomial to four consecutive integral values of  $K_x$ . When this expression is substituted in formula (39), the latter reduces to:

$$f_x = \frac{1}{2} - \frac{D_{x-1} - D_{x+1}}{24D_x}$$

This formula was not considered suitable for age 1 because of the very large difference between  $K_0$  and  $K_1$ , and accordingly the following unsymmetrical formula was derived by fitting a third degree polynomial to the values of  $K_{\frac{1}{2}}$ ,  $K_1$ ,  $K_2$ , and  $K_3$ :

$$\int_0^1 K_{x+t} dt = \frac{1}{180} (-64K_{\frac{1}{2}} + 165K_1 + 84K_2 - 5K_3)$$

The values so obtained are shown in table BF.

TABLE BF.—ESTIMATED SEPARATION FACTORS FOR AGES 1, 2, AND 3, OBTAINED BY APPROXIMATE INTEGRATION: UNITED STATES, 1939-1941

AGE	Separation factors used by Glover	SEPARATION FACTORS OBTAINED BY APPROXIMATE INTEGRATION					
		White		Negro		Other races	
		Male	Female	Male	Female	Male	Female
1.....	0.410	0.399	0.404	0.387	0.392	0.415	0.406
2.....	.470	.450	.446	.431	.434	.428	.431
3.....	.480	.474	.474	.464	.470	.448	.450

In interpreting these results, it must be remembered that the values which are being compared with Glover's values have been obtained by a method which is not only rough, but is also based on assumptions which are likely not to be exactly fulfilled. It may be mentioned also that a moderate change in the values of the separation factors affects the value of the mortality rate only minutely. Therefore, the results obtained are considered satisfactorily close to Glover's values, except perhaps in the numerically unimportant group of "other races," where the data are too scanty, in any case, to yield reliable results.

## UNITED STATES LIFE TABLES AND ACTUARIAL TABLES

**B. DERIVATION OF THE SPECIAL EXTENSIONS  
OF THE KARUP-KING FORMULA USED FOR  
INTERPOLATION OF MORTALITY RATES AT  
AGES 5 TO 11 AND 26 TO 31**

As explained on pages 125 and 126 of part V, the rates of mortality in the various life tables were interpolated by Jenkins' modified fifth difference interpolation formula at ages 32 and over, and by the Karup-King formula at ages 12 to 27, while the rates for ages 0 to 4 were calculated directly from detailed statistics for the individual years of age. The rates for ages 5 to 11 were interpolated from a special third degree curve determined so as to reproduce the calculated rates of mortality at ages 4, 7, and 12, and to have the same first derivative at age 12 as the Karup-King curve used for interpolation in the age interval 12 to 17. Similarly, the rates for ages 28 to 31 were interpolated from a special third degree curve determined so as to have the same ordinate and the same first derivative at age 27 as the Karup-King curve used for interpolation in the age interval 22 to 27, and the same ordinate and first derivative at age 32 as the Jenkins curve employed in the interval 32 to 37. By a suitable artificial extension of the series of pivotal rates of mortality, it was possible to simplify the numerical work by regarding these two special third degree curves as merely continuations of the interpolation by the Karup-King formula. It is the purpose of this section to explain how these artificial extensions were arrived at.

If the Karup-King formula (formula (35), p. 126) were to be used in the regular way in the age interval 7 to 12, the formula would be:

$$q_{7+t} = \frac{s}{5}q_7 + \frac{s^2(s-5)}{250}\delta^2q_7 + \frac{t}{5}q_{12} + \frac{t^2(t-5)}{250}\delta^2q_{12} \quad (40)$$

where  $s=5-t$ , and the requirements as to reproduction of the calculated values of  $q_7$  and  $q_{12}$  and equality of the derivatives at age 12 would be automatically satisfied, no matter what value of  $\delta^2q_7$  is used. Therefore, it is proposed to use instead of the actual value of  $\delta^2q_7$  an artificial value  $\epsilon$  determined so that the formula will reproduce the value of  $q_4$ . Setting  $t=-3$  in formula (40) then gives:

$$q_4 = 1.6q_7 + .768\epsilon - .6q_{12} - .288\delta^2q_{12}$$

Solving for  $\epsilon$  and, at the same time, substituting  $\delta_2q_{12}=q_{17}-2q_{12}+q_7$  gives:

$$\epsilon = \frac{1}{96}(125q_4 - 164q_7 + 3q_{12} + 36q_{17}) \quad (41)$$

Formula (40), with  $\delta^2q_7$  replaced by a value of  $\epsilon$  computed from formula (41) was used not only in the interval 7 to 12, but for ages 5 and 6 as well.

In deriving the special formula used between ages 27 and 32, the pivotal rates of mortality will be denoted by "Q" and the interpolated rates (including the pivotal rates at ages 22 and 27 reproduced by the Karup-King formula and the adjusted rates obtained at the pivotal ages 32, 37, and 42 by Jenkins' formula) will be denoted by " $q$ ." The special formula for interpolation between 27 and 32 can be written in the Karup-King form:

$$q_{27+t} = \frac{s}{5}q_{27} + \frac{s^2(s-5)}{250}\delta^2q_{27} + \frac{t}{5}q_{32} + \frac{t^2(5-t)}{250}\epsilon \quad (42)$$

where  $\epsilon$  denotes an artificial value to be used instead of  $\delta^2q_{32}$ . The conditions as to equality of ordinates and derivatives at age 27 and equality of ordinates at age 32 are automatically satisfied, regardless of the value of  $\epsilon$ . Therefore,  $\epsilon$  will be determined so as to secure equality of the derivatives at age 32. Differentiating formula (42) with respect to  $t$  and setting  $t=5$  gives:

$$q_{32}' = -\frac{1}{5}q_{27} + \frac{1}{5}q_{32} + \frac{1}{10}\epsilon$$

Since  $q_{27}=Q_{27}$  and

$$q_{32}=Q_{32}-\frac{1}{36}\delta^4Q_{32}$$

this may be written:

$$q_{32}' = -\frac{1}{5}Q_{27} + \frac{1}{5}Q_{32} - \frac{1}{180}\delta^4Q_{32} + \frac{1}{10}\epsilon \quad (43)$$

On the other hand, the Jenkins formula to be used for interpolation between 32 and 37 may be written as

$$q_{32+t} = \frac{s}{5}\left(Q_{32} - \frac{1}{36}\delta^4Q_{32}\right) + \frac{s(s^2-25)}{750}\left(\delta^2Q_{32} - \frac{1}{6}\delta^4Q_{32}\right) + \frac{t}{5}\left(Q_{37} - \frac{1}{36}\delta^4Q_{37}\right) + \frac{t(t^2-25)}{750}\left(\delta^2Q_{37} - \frac{1}{6}\delta^4Q_{37}\right)$$

Differentiating with respect to  $t$  and setting  $t=0$  gives:

$$q_{32}' = -\frac{1}{5}Q_{32} - \frac{1}{15}\delta^2Q_{32} + \frac{1}{60}\delta^4Q_{32} + \frac{1}{5}Q_{37} - \frac{1}{30}\delta^2Q_{37} \quad (44)$$

Equating formulas (43) and (44) and solving for  $\epsilon$  gives:

$$\epsilon = 2Q_{27} - 4Q_{32} - \frac{2}{3}\delta^2Q_{32} + \frac{2}{9}\delta^4Q_{32} + 2Q_{37} - \frac{1}{3}\delta^2Q_{37}$$

Upon substituting the expressions in terms of ordinates for the differences appearing in this formula, it becomes:

$$\epsilon = \frac{1}{9}(2Q_{22} + 4Q_{27} - 15Q_{32} + 10Q_{37} - Q_{42})$$

This gives the value of  $\epsilon$  to be employed in formula (42).
