Figure: Algorithm to assist in the interpretation of influenza testing results and clinical decision-making during periods when influenza viruses are NOT known to be circulating in the community

**Influenza positive result (Influenza A or B)**

**Interpretation**
Influenza virus infection is possible if there is an epidemiologic link to an influenza outbreak or recent travel to areas where influenza viruses are circulating. Positive results for influenza A can also be due to novel influenza A virus infection from recent exposure to pigs or birds. Consider potential for a false positive result.

**Actions**
* Use clinical signs and symptoms, medical history, physical examination, travel history, and assess for any epidemiological link to influenza to decide if influenza virus infection is likely. Initiate antiviral treatment as soon as possible, if clinically indicated.
* Implement infection prevention and control measures
* Consider additional influenza virus testing if confirmation is desired or if subtyping of influenza A virus, or distinguishing between influenza A and B viruses is needed, or more specific analyses are needed.
* Consider additional diagnostic testing for other pathogens and/or empiric treatment of bacterial co-infection, if indicated.

**Influenza negative result**

**Interpretation**
Influenza virus infection is unlikely if specimen was collected <4 days after illness onset and there is no epidemiologic link to an influenza outbreak or travel to areas where influenza viruses are circulating. Consider potential for a false negative result.

**Actions**
* Use clinical signs and symptoms, medical history, physical examination, travel history, and assess for any epidemiological link to influenza to decide if influenza virus infection is still suspected, including novel influenza A virus infection, and if antiviral treatment is indicated.
* Initiate antiviral treatment as soon as possible if influenza is still suspected and the patient is at high risk for influenza complications, has progressive disease, or is being admitted to the hospital, without waiting for the results of additional influenza testing.
* Consider the potential for a false negative result and consider additional confirmatory influenza testing by a molecular assay if indicated.
* Consider additional diagnostic testing for other pathogens and/or empiric treatment of bacterial co-infection, if indicated.
1. During periods when influenza activity is low and there is low influenza virus circulation among persons in the community, the positive predictive value of influenza tests is low (that is, the chance that a positive result indicates that the patient has influenza is low – consider potential for a false positive result), and the negative predictive value is high (the chance that a negative result indicates that the patient does not have influenza is high – likely true negative result). Even though most influenza tests have high specificity, false positive results are more common when influenza activity is low. During periods when influenza viruses are not circulating in the community, confirmation of positive results of antigen detection assays (rapid influenza diagnostic test or immunofluorescence assay) should be considered by RT-PCR or other molecular assays, and the local or state health department should be consulted.

2. It is important to ascertain if the patient has an epidemiological link to influenza virus exposure. Is the patient linked to an influenza outbreak (e.g. institutional outbreak, organized group tour outbreak - cruise ship/bus/train, summer camp outbreak) or has the patient or any sick contacts had recent travel to an area where influenza viruses are circulating (e.g. temperate climate countries in the Southern Hemisphere, tropical or subtropical climate countries)?

3. Influenza virus infection may include seasonal influenza A (H3N2), A(H1N1)pdm09, influenza B, or rarely, novel influenza A virus infection. The interpretation of a positive influenza testing result will, in part, depend on the test used – some tests only detect influenza A virus, some will detect influenza B virus and some will detect both A and B viruses. If tests for both influenza A and influenza B are positive, refer specimen to a public health laboratory for resolution, as dual infections are uncommon.

4. Most available tests do not distinguish between influenza A virus subtypes, and cannot distinguish between seasonal influenza A viruses and novel influenza A viruses, and may not detect all novel influenza A viruses. If subtyping is needed, specimens should be sent to a state public health laboratory. If there has been recent exposure to pigs or birds (poultry or wild birds) or to a sick person with such animal exposures and novel influenza A virus infection is suspected, the state health department should be notified immediately and specimens should be forwarded for RT-PCR at the state health department. See Avian Influenza: Information for Health Professionals and Laboratorys and Variant Influenza Viruses: Background and CDC Risk Assessment and Reporting for more information.

5. Antiviral treatment is recommended for outpatients who are at high-risk for influenza complications, persons with progressive disease, and all hospitalized patients with influenza. See Influenza Antiviral Medications: Summary for Clinicians for more information.

6. See: Prevention Strategies for Seasonal Influenza in Healthcare Settings

7. Consult the local or state health department or other sources (e.g., virology testing at a local hospital) for local activity on other respiratory pathogens associated with acute respiratory illness. Empiric antibiotic coverage in hospitalized patients should consider coverage for *Streptococcus pneumoniae*, *Staphylococcus aureus* (including MRSA), *Group A Streptococcus*, and others, especially for hospitalized adult patients per IDSA/ATS CAP guidelines.

8. Respiratory specimens should be collected as close to illness onset as possible to maximize detection of influenza viruses. Influenza viral shedding in the upper respiratory tract declines after about 3-4 days in most people. Infants, young children, immunocompromised patients can shed influenza viruses for longer duration. Molecular assays can detect influenza viral RNA for longer periods than antigen detection assays. If the patient is critically ill on invasive mechanical ventilation, and has tested negative on an upper respiratory tract specimen, including by a molecular assay, a lower respiratory tract specimen (endotracheal aspirate or bronchioalveolar lavage fluid) should be collected for influenza testing by RT-PCR or other molecular assays. See Influenza Virus Testing Methods for more information.

9. If the influenza test used is an antigen detection assay (rapid influenza diagnostic test or immunofluorescence assay) that has suboptimal sensitivity to detect influenza virus in respiratory specimens compared to a “gold standard test” such as RT-PCR or viral culture, a negative result does not exclude influenza virus infection and could be a false negative result if a history of exposure to influenza viruses is identified and the patient has signs and symptoms or complications consistent with influenza. If influenza is still suspected, confirmation of a negative result of an antigen detection assay by RT-PCR or other molecular assays should be considered, and the local or state health department should be consulted. Do not use negative results of antigen detection assays exclusively for clinical decision-making, or for public health decisions, including identifying influenza outbreaks, or for decisions on implementation of infection prevention and control measures.
