Section headings in the COVID-19 Science Update align with the CDC Science Agenda for COVID-19.

PEER-REVIEWED

Key findings:

- With no SARS-CoV-2 testing or screening (base case scenario), there would be 649 (95% uncertainty interval [UI] 505-950) actively infectious passengers on the day of travel among 100,000 passengers and 8,357 (95% UI 6,144-12,831) infectious days (Figure). Compared with the base case:
  - Pre-travel PCR testing alone would reduce expected infectious days by 36% (95% UI 29%-41%) or, with the addition of post-travel quarantine and PCR, by 70% (95% UI 64%-75%).
  - Day of travel rapid antigen testing alone would reduce expected infectious days by 32% (95% UI 26%-38%) or, with the addition of post-travel quarantine and PCR, by 63% (95% UI 58%-66%).
  - Post-travel PCR testing alone would reduce the number of infectious days by 42% (95% UI 35%-49%).

Methods: Microsimulation model of SARS-CoV-2 transmission in a hypothetical cohort of 100,000 US domestic airline travelers to evaluate the effectiveness of routine testing and quarantine strategies on passenger and population level SARS-CoV-2 risk over the travel period. The model incorporated publicly available data on COVID-19 clinical cases, published natural history parameters, and a daily incidence of 150 infections per 100,000 people. Limitations: High adherence to testing, quarantine and self-isolation was assumed; model was static and did not differentiate risk of flights by size or duration; analysis did not include effects of vaccination.

Implications: Testing for SARS-CoV-2 with a rapid antigen test on the day of departure or RT-PCR 3 days before departure could reduce the risk of transmission during travel. The addition of post-travel testing, and 5-day quarantine could further reduce importation and ongoing transmission in the destination city, especially for travel from high to low incidence settings.
Figure:

![Graph showing predicted number of cumulative SARS-CoV-2 infectious days](image)

*Note: Adapted from Kiang et al. Predicted number of cumulative SARS-CoV-2 infectious days (y axis) over the travel period under different test-and-travel strategies. The x axis shows the time over the simulation (in days) relative to the day of travel (vertical dashed line). Solid lines show the mean and shaded areas the 95% uncertainty interval (UI) across 3,000 simulations. ### Vaccination in Health Care Workers

Vaccine efficacy reported from clinical trials may not be replicated in real world settings. Here we present findings from 2 studies (Keehner *et al.* and Shah *et al.* conducted among health care workers, who were among the first to receive SARS-CoV-2 vaccines.

**PEER-REVIEWED**

**Key findings:**
- Two weeks or more after health care workers (HCWs) at the University of California, San Diego (UCSD) and the University of California, Los Angeles (UCLA) received a 2nd dose of mRNA vaccine, SARS-CoV-2 incidence was rare (positivity rate = 0.05%).
- Risk of testing positive for SARS-CoV-2 after vaccination was 1.19% among UCSD HCWs and 0.97% among UCLA HCWs.
Methods: Between December 16, 2020 and February 9, 2021, 36,659 HCWs at UCSD and UCLA received the 1st dose of vaccine; 28,184 of these persons received the 2nd dose. At UCSD, in addition to testing symptomatic persons, mandated weekly testing of asymptomatic persons began December 2, 2020. UCLA instituted an optional testing programs for HCWs on December 26, 2020. Limitations: Results from HCWs may not be generalizable; did not differentiate by vaccine.

PREPRINTS (NOT PEER-REVIEWED)

Key findings:

- Among different health care roles, the strongest association between vaccination and documented COVID-19 cases was seen in healthcare workers (HCWs) with patient-facing roles (hazard ratio [HR] 0.42, 95% CI 0.38-0.47) (Figure).
- Vaccinating HCWs was associated with a reduction in documented COVID-19 cases among household members (HR 0.70, 95% CI 0.63-0.78).

Methods: Cohort study of 144,525 HCWs and 194,362 household members in Scotland between December 8, 2020 and March 3, 2021. COVID-19 cases and hospitalizations were documented in vaccinated and unvaccinated HCWs and household members. Limitations: Household members could be infected via other routes, and thus the 30% relative risk reduction could be an underestimate.

Note: Adapted from Shah et al. HR for documented COVID-19 from 14 days onwards post first dose in healthcare workers compared to the unvaccinated period by age, sex, healthcare role, and deprivation (SIMD: Scottish Index of Multiple Deprivation). Licensed under CC BY 4.0.

Implications for both studies (Keehner et al. and Shah et al.): Data from large studies of HCWs in the US (Keehner et al. and Daniel et al.), Scotland, and Israel show that vaccination is effective at reducing SARS-CoV-2 incidence in a real world setting. Shah et al. found that SARS-CoV-2 vaccination also reduced documented cases and hospitalization in household members.
Detection, Burden, and Impact

PEER-REVIEWED

Key findings:
- Compared to digital contact tracing, manual contact tracing is more efficient in limiting the height of the epidemic peaks and reducing the number of individuals who need to isolate.
- Where both protocols are adopted simultaneously, manual contact tracing leads to a considerable reduction of transmission even considering delays and scalability, while the digital protocol produces a relevant contribution only for large adoption rates.
- Superspreaders’ multiple contacts provide many opportunities to trace them manually, but members of a social network might be similar to each other in decisions to use a contact tracing app or not; networks not adopting the app are completely invisible to digital contact tracing.

Methods: Modeled effectiveness of digital (app-based) and manual (interview-based) contact tracing using parameters tailored for SARS-CoV-2 diffusion within the activity-driven model, a general empirically validated framework for network dynamics. Limitations: Costs and practical concerns need to be considered when using digital or hybrid contact tracing strategies.

Implications: Digital contact tracing should only be used in combination with manual contact tracing and cannot be considered simply a cheaper and more rapid way of implementing standard contact tracing.

Transmission

The B.1.1.7 Variant

PREPRINTS (NOT PEER-REVIEWED)

The B.1.1.7 variant was first identified in the U.K. and has increasingly been reported in the US.

Key findings:
- Two dominant waves of hospital admissions with SARS-CoV-2 were detected.
  - The proportion of admissions with the B.1.1.7 variant increased during the second wave and accounted for 97% of sequenced isolates in January 2021 (Figure).
- Patients with the B.1.1.7 variant more frequently had hypoxia on admission than patients with non-B.1.1.7 variants (70.0% vs. 62.5%).
Methods: Electronic health record data from a multisite inner-city London hospital for all SARS-CoV-2 cases (n = 5,810) between March 13, 2020 and February 17, 2021 were linked with viral sequencing data. Limitations: Results may not be generalizable to other clinical settings.

Figure:

Note: Adapted from Snell et al. Number of cases with sequenced SARS-CoV-2 isolates by epi-week and the proportion with B.1.1.7 from March 13, 2020 (2020w11) through February 17, 2021 (2021w8). Licensed under CC-BY-NC-ND 4.0.

B. Rapid, widespread, and preferential increase of SARS-CoV-2 B.1.1.7 variant in Houston, TX, revealed by 8,857 genome sequences. Musser et al. medRxiv (March 24, 2021).

Key findings:
- There was a rapid, widespread increase of the B.1.1.7 SARS-CoV-2 variant (Figure):
  - Case doubling time was estimated to be 6.91 days (95% CI 5.02-11.08).
  - 648 cases with variant B.1.1.7 were identified; none had the E484K mutation.
- No significant difference in patient age, gender, median length of hospitalization, or mortality was observed between cases with and without the B.1.1.7 variant.

Methods: Identified variants of concern based on sequence data from 8,857 SARS-CoV-2 patient samples from the Houston Methodist hospital system, representing 4.8% of reported COVID-19 cases in metropolitan Houston between January 1 and March 7, 2021. Limitations: One hospital system within a limited geographical area; sample likely underrepresents pediatric patients and patients with challenges accessing care.
Implications for both studies (Snell et al. and Musser et al.): The rate of increase in COVID-19 cases with the B.1.1.7 variant in 2 areas highlights its increased transmissibility; some data (Snell et al.; Grint et al.) suggest increased illness severity, reinforcing the urgency of vaccination and other mitigation efforts.

The effect of in-person primary and secondary school instruction on county-level SARS-CoV-2 spread in Indiana. Bosslet et al. medRxiv (March 20, 2021). Published in Clinical Infectious Diseases as The Effect of In-Person Primary and Secondary School Instruction on County-Level Severe Acute Respiratory Syndrome Coronavirus 2 Spread in Indiana (January 1, 2022).

Key findings:
- 70,021 SARS-CoV-2 cases were reported from 73 Indiana counties between July 12 and October 6, 2020, averaging 805 cases per day (Figure).
- In-person primary and secondary school instruction was associated with a small but significant daily increase in SARS-CoV-2 cases/100,000 residents in the county 28 days later.
  - A 10-percentage point increase in in-person instruction was predicted to increase daily new cases by 0.80%.

Methods: Evaluated association of proportion of students returning to in-person learning with community-wide daily SARS-CoV-2 cases per 100,000 residents at the county level in Indiana between July 12 and October 6, 2020 using a panel regression analysis, accounting for differences in masking and distancing enforcement. Included 73 of 92 Indiana counties, accounting for 85.7% of school corporations and 90.6% of student enrollment statewide.

Limitations: Incomplete data on proportion of in-person instruction in each county; assumed proportion of
students attending school in-person was constant over the analytic period; insufficient data to examine effects by grade or age.

**Implications:** Findings suggest in-person schooling might increase community transmission, but to a lesser extent than other indoor gatherings. Data from this and another recent study in Canada (Bignami-van Assche et al.) support implementing precautions, including physical distancing and face coverings, when opening schools.

**Figure:**

Note: Adapted from Bosslet et al. Average daily new SARS-CoV-2 cases over time for study counties including timeline of stages of Indiana re-opening, study period window, and window of schools re-opening. Licensed under CC-BY-NC-ND 4.0.

**Natural History of SARS-CoV-2 Infection**

**PEER-REVIEWED**

**Association of age with SARS-CoV-2 antibody response.** Yang et al. JAMA Network Open (March 22, 2021).

**Key findings:**
- Seroprevalence among pediatric (16.5%, 95% CI 14.4%-18.7%) and adult (18.6%, 95% CI 18.2%-19.1%) populations was similar.
- SARS-CoV-2 IgG levels showed negative correlation with age in the pediatric population ($r = -0.45$, $p <0.001$) and positive correlation with age in adults ($r = 0.24$, $p <0.001$) (Figure).
- In patients ages 1 to 24 years, SARS-CoV-2 IgG and total antibody levels, neutralizing activity, and avidity were negatively correlated with age.

**Methods:** Cross-sectional study including 31,426 SARS-CoV-2 antibody tests performed between April 9, 2020 and August 31, 2020 from pediatric (1–18 years) and adult (>18 years) inpatients and outpatients at a New York City hospital. Semiquantitative IgG levels from a subsample (85 pediatric and 3,648 adult patients) were compared
between age groups. **Limitations:** Selection bias for testing given retrospective study using existing data; unknown time between disease onset and antibody testing.

**Implications:** Unexpectedly, patients ages 19–30 years showed lower antibody responses to SARS-CoV-2 than children and older adults. Differing antibody responses in pediatric and adult populations suggests that differences in clinical manifestations between these two groups may be due in part to age-related immune responses, potentially necessitating age-targeted strategies for disease screening and vaccine development.

**Figure:**

Note: Adapted from Yang et al. SARS-CoV-2 IgG levels from SARS-CoV-2 positive pediatric (n = 85) and adult (n = 2,648) patients. Lines show correlation between SARS-CoV-2 level and age. Licensed under CC BY.

**Seroprevalence and humoral immune durability of anti-SARS-CoV-2 antibodies in Wuhan, China: a longitudinal, population-level, cross-sectional study.** He et al. The Lancet (March 20, 2021).

**Key findings:**
- More than 50,000 COVID-19 cases were reported in Wuhan as of April 8, 2020, when lockdown was lifted; few cases were reported after this date (Figure).
- Baseline seroprevalence among Wuhan residents was 6.92% (95% CI 6.41%-7.43%):
  - 40% of antibody-positive individuals had neutralizing antibodies detected.
  - >80% of antibody-positive individuals were asymptomatic.
- Levels of neutralizing antibodies did not significantly decrease over the study period.

**Methods:** Multistage, population-stratified, cluster random sample (n = 9,702) in Wuhan, China, of persons residing there for at least 14 days since December 1, 2019. Pan-immunoglobulin detection and neutralizing antibody activity were measured at baseline (April 2020, after the lockdown), and at two subsequent timepoints (June, and October–December 2020). **Limitations:** Uncertain when individuals were infected relative to antibody testing; may not be generalizable to other communities.

**Implications:** While neutralizing antibody activity in previously infected individuals remained at a relatively stable level for months, most individuals were still susceptible to SARS-CoV-2 infection after the epidemic subsided in
Wuhan. These findings highlight the need for vaccinations as the main driver of protection against SARS-CoV-2 infection, as natural infection alone is unlikely to lead to community level protection.

Figure:

Note: Adapted from He et al. Timeline of new reported cases in Wuhan, China, and the follow-up period. The shaded area shows the time period when 75% of confirmed cases were identified. Reprinted from The Lancet, Vol 397, He et al., Seroprevalence and humoral immune durability of anti-SARS-CoV-2 antibodies in Wuhan, China: a longitudinal, population-level, cross-sectional study, p. 1075-1084. Copyright (2021), with permission from Elsevier.

Social, Behavioral, and Communication Science

PEER-REVIEWED

Key findings:
- Support for social distancing decreased from 89% in April to 79% in July but remained steady at 78% in November 2020.
- In July and November, most respondents supported mask wearing (80% and 79%, respectively) and contact tracing (74% and 73%, respectively).
• Differences in support for social distancing (Figure) and other mitigation efforts were most pronounced by age, political affiliation, and trust in science.

Methods: Survey conducted among a nationally representative cohort of US adults in April (n = 1,468), July (n = 1,337), and November (n = 1,222) 2020 using a 5-point Likert scale to measure support for COVID-19 mitigation efforts by political partisanship, trust in science, and fixed (e.g., prioritizing social order and hierarchies) vs. fluid (e.g., valuing independence and self-reliance) worldview. Limitations: Loss to follow-up differed by demographics, education, income, and support of social distancing.

Implications: This study highlights challenges in reaching key groups to help mitigate the spread of COVID-19. Developing persuasive communication efforts for those distrusting science should be a priority.

Figure:

Note: Adapted from Barry et al. The figure shows support of social distancing (point estimates and 95% CI) in April, July, and November 2020. Used by permission of The Sheridan Press.

In Brief

Detection, Burden, and Impact

• Rennert et al. Surveillance-based informative testing for detection and containment of SARS-CoV-2 outbreaks on a public university campus: an observational and modelling study. Lancet Child & Adolescent Health (March 19, 2021). A novel surveillance-based informative testing strategy, consisting of random testing to identify outbreaks in residence hall buildings or floors and targeting students for follow-up testing, is an effective and feasible strategy to mitigate disease spread in university settings.

• Conlon et al. Impact of the influenza vaccine on COVID-19 infection rates and severity. American Journal of Infection Control (February 22, 2021). Influenza vaccination, in this study within the Michigan Medicine
healthcare system, was associated with reduced odds of testing positive for COVID-19 (aOR = 0.76, 95% CI 0.68-0.86) and improved clinical outcomes. (Figure).

Figure:

**Effect of Vaccination Status on Clinical Outcomes**

![Chart showing the effect of vaccination status on clinical outcomes](chart.png)

*Note:* Total cohort includes all patients who tested positive for COVID-19 in this medical system, stratified by those who received no influenza vaccine (n = 693) or received influenza vaccine (n = 525). Mechanical ventilation, intensive care, and length of stay assessed only for those who were hospitalized (n = 505). All clinical outcomes adjusted for baseline covariates. * signifies p <0.05.
