IN THIS REPORT is contained weight by height information for American adults as determined from Health Examination Survey findings in 196062. For the Survey a probability sample of 7,710 persons was selected to represent the 111 million adults in the U.S. civilian, noninstitutional population aged 18-79 years. Of these, 6,672 adults, or more than 85 percent, were examined.

National estimates based onfindings of weight by single inches of height for men and women within the various age groups in the study are included. Averages and certain percentiles are shown to describe the distributions of weight for given height.

Comparison of these findings is made with three studies on which widely used height-weight standards are based: The 1959 Society of Actuaries study in the United States and Canada, the 1953 Canadian height-weight survey, and the 1943 British height-weight survey.

The study shows that in general American men range in average weight from 146 pounds at 62 inches in height to 190 pounds at 73 inches; while for American women this average progresses from 129 pounds at 58 inches to 157 pounds at 67 inches.

Adults in the United States weigh 5 to 6 pounds more on the average than their Canadian counterparts did in 1953, 14 to 19 pounds more than the British in the study findings of 1943, and 6 to 11 pounds more than insured Americans in the 1959 study of the Society of Actuaries. Comparisons are made without adjustments for clothing.

# WEIGHT BY HEIGHT AND AGE OF ADULTS 

Jean Roberts, Division of Health Examination Statistics

## INTRODUCTION

This report presents additional weight and height findings among adults in the United States as determined in the Health Examination Survey during 1960-62.

The Health Examination Survey from which these data come is one of three programs of the National Health Survey. It collects such data as can best or only be secured by direct examination, tests, and measurements, using a nationwide probability sample of individuals. Other programs of the National Health Survey obtain health related data through household interview and through available medical records.

The first cycle for the Health Examination Survey was concerned mainly with the determination of the prevalence of certain chronic diseases, dental health status, and the distribution of certain sensory and other physiological and anthropometric characteristics among the adult civilian, noninstitutional population of the United States. During the study, which extended from October 1959 through December 1962, 6,672 persons were examined out of a nationwide probability sample of 7,710 persons 18-79 years of age selected from the 111 million of the population in that age group. Medical and other Survey staff performed the standard examination, which lasted about 2 hours, in mobile clinics specially designed for this purpose.

Previous publications in this series describe the general plan and initial program of the Health Examination Survey, ${ }^{1}$ the sample population, the response, and the effect of nonresponse on the findings. ${ }^{2}$

An introductory report on weight, height, and certain of the other physical measurements obtained in this cycle has already described the measurement techniques used and the distributions of those measurements in the population by age and sex. ${ }^{3}$

This reportpresents national estimates based on findings of weight by single inches of height for men and women within the various age groups included in the study. Averages and certain percentiles are used to describe the curves of weight. A brief explanation of the estimation methods used in smoothing these data is also included.

Comparison of these findings is made with three studies on which widely used height-weight standards are based: the 1959 Society of Actuaries study in this country and Canada, the 1953 Canadian height-weight survey, and the 1943 British height-weight survey.

## The Measurements

As previously reported, all measurements were made with the examinee stripped to the waist and without shoes but wearing paper slippers and a lightweight, knee-length examining gown.

Weight, obtained with the examinee standing without support on the platform of an automatic balancing scale, was recorded immediately as the record was inserted in the scale's automatic printer. Weight was read off the record to the nearest half pound. A small series of representative clothing, checked following the study, showed the weight of men's clothing worn in the examination to be slightly over 2 pounds and that of women's clothing to be slightly less than 2
pounds. The values presented in this report are shown as measured and are not corrected for clothing.

For height measurement, the examinee stood erect on a horizontal platform with his back against a vertical 3 -inch-wide measuring scale, looking straight ahead with his head in the Frankfort horizontal plane. A horizontal measuring bar ( $1 / 1 / 2$ inches wide) was then brought down snugly but not tightly on the top of the head. An adhesive strip with the examinee's case number was attached to the scale's pointer support and the position of the pointer on the scale was photographed. For examinees over 75 inches, who were too tall to be photographed, height was measured with an anthropometer. The examinee stood erect on the floor, heels together, looking straight ahead with his head in the Frankfort horizontal plane, arms hanging at his sides. The anthropometer was held perpendicular to the
floor in the midline of the examinee's back, and the movable bar was brought down into firm contact with the top of the head, compressing the hair if necessary. Height recordings in millimeters were used and then converted mechanically to measurements in tenths of an inch.

## FINDINGS

The average weight among American men ranges from 146 pounds for those 62 inches in height to 190 pounds for those 73 inches tall and only slightly less for men measuring 74 inches, as estimated from the Health Examination Survey findings in 1960-62 for the adult civilian, noninstitutional population of the United States 18-79 years of age (table 1 and fig. 1).

Among American women, these findings show average weight ranges from 129 pounds at 58 inches to 157 pounds at 67 inches. Weights at

Figure 1. Unadjusted mean and median weight at each inch of height for men and women $18-79$ years of age.
the extremes of the height range for which reliable estimates could be made deviated from this expected pattern somewhat. Those measuring 57 inches weighed 5 pounds more on the average than those 1 inch taller, while the tallest groupstature of 68 inches-averaged 3 pounds less than those 1 inch shorter, reflecting in part the greater sampling variability at these extremes.

Some indication of the variation in weight among individuals of the same height and age is shown by the range between the 25 th $\left(Q_{1}\right)$ and the 75th $\left(\mathrm{Q}_{3}\right)$ percentiles in table 2-the first of these points being the weight not exceeded by 25 percent of persons of the given height, age, and sex and the second the weight equaled or exceeded by 25 percent of that group. This range, which includes 50 percent of the population, varies between 29 and 43 pounds and averages 35 pounds over the height range for both men
and women, with no consistent pattern related to height.

Within each age group, the average weight tends to increase with height. Deviations from an orderly progression with ' respect to this, in general, probably reflect sampling error rather than any real weight difference in the population groups from one height interval to the next.

For persons taller or shorter than the extremes of the height range shown, the sample was too small to provide reliable estimates of the distribution of weights in the population. More complete weight and height distributions which contain some further information on these extremes are shown in tables 3 and 4.

The distribution of weight for any given height tends to be positively skewed with greater deviations existing above than below the average weight as reflected by the fairly consistent ex-

Figure 2. Unadjusted means and means from regression equations for weight at each inch of height for men and women 18-79 years of age.
cess of mean over median weights shown in figure 1.

While it is evident that the relationship between height and weight is not strictly linearthat is, weight does not increase precisely in set increments with increased height-the exact relationship, if it could be satisfactorily determined, would differ somewhat for each group. Yuan (1933) ${ }^{4}$ suggested that the bivariate distribution of weight by height could be fitted by a logarithmic surface. However, Kemsley (1952) ${ }^{5}$ tested this proposal on the height-weight data for the civil population in Great Britain obtained during 1943 and found the fit for that population to be poor. It seriously underestimated the variance of the distribution of weight for short heights and overestimated it for tall heights.

He found no way of improving the fit or making it suitable for graduation on the British data.

In this report, for the purposes of smoothing the findings from the present study and for making comparisons with other surveys on which certain existing height-weight standards are based, the regression of weight on height has been treated as linear.

Linear regression equations of weight on height have been fitted by the least squares method for each of the 14 age-sex groups included in the study (see Appendix). From these were obtained the smoothed averages shown in table 5. The differences between these and the averages obtained directly from the data are generally negligible (figs. 2 and 3), averaging less than half a pound over the height range.

Figure 3. Average difference over height range between unadjusted mean weights and mean weights from regression equations for men and women, by age.

The only exceptions are for persons in the age groups $35-44$ and $55-74$ years, where the average deviation extends from 2 pounds among men 35-44 years of age to 6 pounds for women $65-74$ years, due primarily to the influence of the less stable values at the extremes for the height distribution. There is no consistent pattern of poorer agreement for either taller or shorter persons. The correspondence is slightly better for men than for women, but among both groups the averages obtained in this way do not in general differ significantly from those determined by smoothing methods similar to those used in British and Canadian studies.

Also included in table 5 are the two points in the fitted distributions which bound the range of weights centered around the mean (from the regression equation) within which half of the population of a given height will fall. Unlike the 25th and the 75th percentiles, however, slightly more than one-fourth will weigh this or less, and slightly fewer will equal or exceed it.

The height-by-weight distributions of adults in the general population are shown in tables 6-21. Height-weight distributions of examination findings by age for men and women in the Health Examination Survey of 1960-62 are contained in tables I-XIV of the Appendix.

## COMPARISON WITH OTHER HEIGHT-WEIGHT SURVEYS

Comparison is made here of the present findings for the adult population of the United States with those from three studies on which frequently used weight-for-height standards in Great Britain, Canada, and the United States are based.

The British body weight survey of $1943,{ }^{6}$ carried out by the Ministry of Food, obtained the height and weight on a sample of 61,000 men and women 14-79 years of age in the civil population employed in industries of various sizes in England, Scotland, and Wales. Measurements were made in clothing and shoes. Comparison here is with the unadjusted weights and heights contained in Kemsley's report of these findings in 1952. ${ }^{5}$ A subsequent study of Kemsley, Billewicz, and Thomson in 1962, ${ }^{7}$ based on these data, discusses the representativeness of find-
ings from a civilian population during World War II, when so many were in service overseas and rationing was enforced. Subsequent studies have indicated that the effect of wartime rationing on body weight was trivial. Nor did average weight at each height differ significantly among three groups-civilians, those called up for national service, and more recent Army recruits.

In the Canadian height-weight survey of 1953, ${ }^{8}$ measurements were taken on a probability sample of some 22,000 Canadians, 2 years of age and older, in indoor clothing without shoes. Clothing weights for these persons were estimated as averaging 3 pounds for men (ranging from 1.5 to 5 pounds) and. 2 pounds for women (ranging from 1 to 8 pounds).

The 1959 Society of Actuaries study ${ }^{9}$ among several million life insurance policy holders in the United States and Canada during 1935-53 has provided the basis for frequently used heightweight standards in this country. The imperfections in these data-heights and weights not always measured but frequently recorded only as reported verbally by the applicant and the variation in practice as to the amount of clothing worn for the measurements-have been noted in a previous report. ${ }^{3}$

Two factors need to be considered in making comparisons between these studies and the present one. First, the methods used in obtaining the smoothed averages differ somewhat for each study. This apparently will have a negligible effect on the comparability of the findings, however, since smooth averages obtained by applying the various methods to the data from the present study do not differ significantly from the linear regression estimates. The second factor-that of differences in clothing weights-will substantially affect comparability among the various studies. Clothing weights for the Canadian group will be most nearly like those for the present study, averaging about 1 pound more. In the other two studies, average clothing weights are substantially greater-the British were weighed in shoes and the American insurance holders with varying amounts of clothing.

Findings from the present study show adults in the United States generally weighed more on the average than their Canadian or British counterparts in 1953 and 1943, respectively, or than

Figure 4. Average weight, by height for men in the United States, 1960-62; 1959 Society of Actuaries Study; 1953 Canadian survey; and 1943 British survey.

Figure 5. Average weight, by height for women in the United States, 1960-62; 1959 Society of Actuaries Study; 1953 Canadian survey; and 1943 British survey.
the insured Americans in the 1959 study. In the age groups from 18-64 years, Canadian men averaged 5 pounds lighter, the British men 19 pounds less, and the insured American men 6 to 7 pounds less. Among women of this age, the Canadians were 5 to 6 pounds lighter, British 14 to 15 pounds less, and insured Americans 10 to 11 pounds lighter. If adequate compensation could be made for disparities in clothing weight, the differences might be even greater.

The pattern of differences in average weight varies with height and with age, as indicated in figures 4 and 5 . Among the youngest group, 1824 years of age, the differences between averages from the present study and those from the other three diminish as height increases, more rapidly for women than for men. The one exception to this is found among Canadian men, whose average weight maintains a constant difference ranging between 9 and 11 pounds less than that of their counterparts in the United States over the height span.

At 25-34 years of age the pattern is reversed. The difference between the present averages for the United States and the other three studies increase as height increases; the rate of change again is more rapid for women than men.

From 35 years on the patterns of differences are less consistent.

At 35-44 years Canadian men average a fairly consistent 3 to 4 pounds less than presentday counterparts in the States and the British 20 to 21 pounds less, while insured Americans show differences that fall off with increased height. Differences for Canadian women increase with increased stature, while the reverse pattern is seen when comparison is made with the other two groups.

At 45-54 years, average weight difference between women of the United States and those from Canada and Britain becomes greater as height increases. However, Canadian men show a lessening in weight differential with increased stature. Other groups show a fairly constant difference throughout the height span.

By 55-64 years, Canadian men differ little in average weight from those in the United States, while for Canadian women there is some increase
in the difference with increased stature. Both British men and women maintain a fairly constant difference throughout the height range, while insured Americans show diminishing difference with greater stature. In fact, taller insured men (71 inches and over) weighed more on the average ( 4 to 13 pounds more) than pres-ent-day Americans.

The Society of Actuaries study for men 6574 years of age, when compared with present findings, showed average weights less than those in the present study for shorter men, about the same as those for men of medium height, and greater than those for taller men. Among women the differences remain fairly constant at about 9 to 11 pounds less for the insured women throughout the height range. Canadian and British published data for persons 65 years and over include persons beyond the age range of the present study, hence are not strictly comparable.

## SUMMARY

This report contains weight-for-height findings by age among the adult men and women in the civilian, noninstitutional population of the United States aged 18-79 years based on data from the Health Examination Survey in 1960-62. Tables of average weights and the $-25 \mathrm{th}, 50 \mathrm{th}$, and 75th percentiles for adult Americans, estimates from linear regression equations fitted to smooth the irregularities in the data, as well as height-weight distributions by age are-included.

Comparison is made of the findings from the present study with those from three other studies on which frequently used weight-forheight standards in Great Britain, Canada, and the United States are based.

This study shows, in general, that:

1. American men range in average weight from 146 pounds at 62 inches in height to 190 pounds at 73 inches; while for American women this average progresses from 129 pounds at 58 inches to 157 pounds at 67 inches.
2. Within each age group, the average weight tends to increase with increasing heigit. Deviations from an orderly pattern with respect to this, in general, reflect sampling error primarily.
3. While the regression of weight on height (the rate at which weight increases with height) is not strictly linear, linear regression equations gave a better than expected fit when used to smooth the data for comparative purposes and to extend them at the extremes, where the sample was too small to produce reliable estimates.
4. Adults in the United States weigh more on the average than their Canadian and British counterparts in the 1953 and 1943 studies in those countries and than the insured Americans in the 1959 study of the Society of Actuaries. Among men 1864 years of age, Canadians were found to average 5 pounds lighter, British 19 pounds less, and insured Americans 6 to 7 pounds less than American men. For women of this age Canadians were 5 to 6 pounds less, British 14 to 15 pounds lighter, and insured Americans 10 to 11 pounds less than American women.
5. The pattern of differences in average weights between the present study and each of the other three varies with height and age and differs somewhat among each of the three previous studies. Comparisons are made without adjustments for clothing.

${ }^{1}$ Median $-P_{50}$, the percentile below which 50 percent of the population fall.
Quartiles - $P_{25}$ and $P_{75}$, the 25 th and 75 th percentile below which 25 and 75 percent of the population fall.
${ }^{2}$ Height without shoes; weight partially clothed-clothing weight estimated as averaging 2 pounds.

3Estimated values obtained from the linear regression equations.

${ }^{1}$ Estimated values from regression equations of weight on height for specified age groups. The values shown for $P_{25}^{\prime}$ and $P_{75}^{\prime}$ are the points which bound the range of weights around the smoothed average within which 50 percent of the population of a given height would fall. Approximately 25 percent would weigh less and 25 percent more than these average values. (See Appendix.)
${ }^{2}$ Height, without shoes; weight partially clothed-clothing weight estimated as averaging 2 pounds.

## APPENDIX

## STATISTICAL NOTES

## Survey Design

The first cycle of the Health Examination Survey employed a highly stratified multistage probability design in which a sample of the civilian, noninstitutional population of the conterminous United States $18-79$ years of age was selected. At the first stage, a sample of 42 primary sampling units (PSU's) was drawn from among the 1,900 geographic units into which the United States was divided. Random selection was controlled within regional and size-of-urban-place strata into which the units were classified. As used here a PSU is a standard metropolitan statistical area or one to three contiguous counties. Later stages result in the random selection of clusters of typically about four persons from a neighborhood within the PSU. The total sample included some 7,700 persons in 29 different States. The detailed structure of the design and the conduct of the Survey have been described in previous reports.

## Reliability

The methodological strength of the Survey derives especially from its use of scientific probability sampling techniques and highly standardized and closely controlled measurement processes. This does not imply that statistics from the Survey are exact or without error. Data from the Survey are imperfect for three major reasons: (I) results are subject to sampling error, (2) the actual conduct of a survey never agrees perfectly with the design, and (3) the measurement processes themselves are inexact even though standardized and controlled.

The first-stage evaluation of the Survey was reported in reference 2 , which dealt principally with an analysis of the faithfulness with which the sampling design was carried out. This study notes that out of the 7,700 sample persons the 6,670 who were examined-a response rate of over 86 percent-gave evidence that they were a highly representative sample of the civilian, noninstitutional population of the United States. Imputation of nonrespondents was accomplished by attributing to nonexamined persons the characteristics of comparable examined persons as described in reference 2. The specific procedure used amounted to
inflating the sampling weight for each examined person in order to compensate for sample persons at that stand of the same age-sex group who were not examined.

In addition to persons not examined ar all, there were some whose examination was incomplete in one procedure or another. For those persons whose examination was incomplete as regards to height or weight, estimates were made subjectively on the basis of a multiple regression-type decision, substituting for the missing measurements those for an individual who was of the same age, sex, and race and who had other body dimensions similar to the ones available for the examinee with incomplete data. Where no body measurements were available, a respondent of the same age-sex-race group was selected at random and his measurements assigned to the nonexamined person.

Height by weight distributions by age for men and women measured in the Health Examination Survey of 1960-62 are shown in tables I-XIV.

## Sampling and Measurement Error

In the present report, reference has been made to efforts to minimize bias and variability of the measurement techniques.

The probability design of the Survey makes possible the calculation of sampling errors. Traditionally the role of the sampling error has been the determination of how imprecise the survey results may be because they come from a sample rather than from the measurement of all elements in the universe.

The estimation of sampling errors for a study of the type of the Health Examination Survey is difficult for at least three reasons: (1) measurement error and "pure" sampling error are confounded in the data-it is not easy to find a procedure which will either completely include both or treat one or the other separately, (?) the survey design and estimation procedure are complex and, accordingly, require computationally involved techniques for the calculation of variances, and (3) from the survey are coming thousands of statistics, many for subclasses of the population for which there are a small number of sample cases. Estimates of sampling error are obtained from the sample data and are themselves subject to sampling error when the
number of cases in a cell is small or, even occasionally, when the number of cases is substantial.

Estimates of approximate sampling variability for selected statistics used in this report are presented in table XV. These estimates have been prepared by a replication technique which yields overall variability through observation of variability among random subsamples of the total sample. The method reflects both "pure" sampling variance and a part of the measurement variance.

In accordance with usual practice, the interval estimate for any statistic may be considered the range within one standard error of the tabulated statistic, with 68 percent confidence; or the range within two standard errors of the tabulated statistic, with 95 percent confidence.

An overestimate of the standard error of a difference $d=x-y$ of two statistics $x$ and $y$ is generally given by the formula $s_{d}=\left(x^{2} V_{x}^{2}+y^{2} V_{y}^{2}\right) 1 / 2$ where $V_{x}$ and $V_{y}$ are the relative sampling errors, respectively, of $x$ and $y$.

## Small Categories

In some tables magnitude is shown for cells for which the sample size is so small that the sampling error may be several times as great as the statistic itself. Obviously in such instances the statistic has no meaning except to indicate that the true quantity is small. Such numbers, if shown, have been included to convey an impression of the overall story of the table.

## Regression Estimates

For the purpose of smoothing the sample findings in the present study for making estimates within certain cells where the number of examinees of a given age and height was too small to produce sufficiently reliable data, linear regression equations of the form

$$
Y=a+b x
$$

for predicting weight ( $y$ ) in pounds from height ( $x$ ) in inches were fitted by the method of least squares to each of * the 14 age-sex groups in the sample of examinees. The constants-regression coefficient (b) and

Y-intercept(a)-in the regression equations are then of the form

$$
\begin{aligned}
& b=\frac{\Sigma x y-n \bar{x} \bar{y}}{\Sigma\left(x^{2}\right)-n(\bar{x})^{2}} \\
& a=\bar{y}-b \bar{x}
\end{aligned}
$$

where $\bar{x}$ and $\bar{y}$ are the mean values of $x$ and $y$, respectively.

The regression coefficient, indicating the slope of the regression line, here measures the average number of pounds increase in weight which occurs with each inch of increase in height.

The goodness of fit of these regression lines to the observed data is determined by the usual standard error of estimate formula

$$
\bar{S}_{y-x}=\left[\frac{\Sigma(y-Y)^{2}}{n-2}\right]^{1 / 2}
$$

which indicates how nearly the estimated weight values from the regression equations, $Y$, actually agree with the actual observed weight values, $y$.

The resultant constants determined for the regression equations for the 14 age-sex groups and the standard error of estimate around these regression lines are shown in table XVI.

Assuming that weight by height is normally distributed about the fitted regression line, 34.13 percent of the group of examinees of any given height would have weights between the average value ( $Y$ ) determined from the regression line and one standard error of estimate ( $\bar{S}_{y, x}$ ) above (or below) that average. Onefourth of the group could then be assumed to weigh between the mean value and $0.7325 \bar{S}_{y . x}$ above (or below) the mean. These points, $Y \pm 0.7325 \bar{S}_{y, x}$, have been designated as smoothed quartile values $P_{25}^{\prime}$ andi $P_{75}^{\prime}$ in table 5 since they bound the range which includes 50 percent of the group of any given height.

The agreement between the height-weight distributions for unweighted data from the entire sample of examinees and those from the inflated national estimates based on them are sufficiently close that the regression equations will provide a reasonable fit to either series. Because of the close agreement between the average weights obtained from the actual measurements and those estimated from the regression equation, the relative sampling errors shown in table XV can be considered as applying to either series.

Table XVI. Constants for linear regression equations fitted to height-weight measurements from the Health Examination Survey, 1960-62

|  | Age-sex group | a | $b$ | $\bar{S}_{y \cdot x}$ |
| :---: | :---: | :---: | :---: | :---: |
|  | Men |  |  |  |
| 18-24 |  | -80.36 | 3.502 | 23.4 |
| 25-34 |  | -135.76 | 4.463 | 26.7 |
| 35-44 |  | -83.80 | 3.750 | 24.6 |
| 45-54 |  | -101.75 | 4.034 | 25.2 |
| 55-64 |  | -74.62 | 3.585 | 27.4 |
| 65-74 |  | -67.92 | 3.419 | 26.3 |
| 75-79 |  | -181.73 | 5.080 | 23.7 |
|  | Women |  |  |  |
| 18-24 |  | -9.86 | 2.205 |  |
| 25-34 |  | -117.10 | 4.010 | 29.5 |
| 35-44 |  | +1.75 -76.50 | 2.271 | 30.3 |
| 45-54 $55-64$ |  | -76.50 -24.79 | 3.600 2.859 | 29.9 |
| 65-74 |  | -24.79 -65.33 | 2.859 3.455 | 29.7 26.1 |
| 75-79 |  | -72.26 | 3.468 | 27.0 |

## OUTLINE OF REPORT SERIES FOR VITAL AND HEALTH STATISTICS

Public Health Service Publication No. 1000
ries 1. Programs and collection procedures. - Reports which describe the general programs of the National Center for Health Statistics and its offices and divisions, data collection methods used, definitions, and other material necessary for understanding the data.

Reports number 1-4
ies 2. Data evaluation and methods research.-Studies of new statistical methodology including: experimental tests of new survey methods, studies of vital statistics collection methods, new analytical techniques, objective evaluations of reliability of collected data, contributions to statistical theory.

Reports number 1-17
fies 3. Analytical studies.-Reports presenting analytical or interpretive studies based on vital and health statistics, carrying the analysis further than the expository types of reports in the other series.

Reports number 1-4
ies 4. Documents and committee reports.-Final reports of major committees concerned with vital and health statistics, and documents such as recommended model vital registration laws and revised birth and death certificates.

Reports number 1 and 2
ies 10. Data From the Health Interview Survey.-Statistics on illness, accidental injuries, disability, use of hospital, medical, dental, and other services, and other health-related topics, based on data collected in a continuing national household interview survey.
Reports number 1-29
es 11. Data From the Health Examination Survey.-Statistics based on the direct examination, testing, and measurement of national samples of the population, including the medically defined prevalence of specific diseases, and distributions of the population with respect to various physicial, physiological, and psychological measurements.

Reports number 1-1.t
es 12. Data From the Health Records Survey. -Statistics from records of hospital discharges and statistics relating to the health characteristics of persons in institutions, and on hospital, medical, nursing, and personal care received, based on national samples of establishments providing these services and samples of the residents or patients.

Reports number 1-4
es 20. Data on mortality. - Various statistics on mortality other than as included in annual or monthly reportsspecial analyses by cause of death, age, and other demographic variables, also geographic and time series analyses.
Reports number 1
es 21. Data on natality, marriage, and divorce. - Various statistics on natality, marriage, and divorce other than as included in annual or monthly reports-special analyses by demographic variables, also geographic and time series analyses, studies of fertility.

Reports number 1-9
es 22. Data From the National Natality and Mortality Surveys. - Statistics on characteristics of births and deaths not available from the vital records, based on sample surveys stemming from these records, including such topics as mortality by socioeconomic class, medical experience in the last year of life, characteristics of pregnancy, etc.

Reports number 1
a list of titles of reports published in these series, write to:
