Subject: FW: Last PAPR Presentation

Karen:

Here is the presentation of one of the Outside Speakers at our Public Meeting in Arlington on April 10th (PAPR, Docket # NIOSH 008)which needs to be included as part of the docket.

Timothy R. Rehak, P.E.
General Engineer
NIOSH-NPPTL

Subject: Last PAPR Presentation

Tim,

Attached are two presentation files from Goran Berndtsson with The Sea Group. This is the presentation we have been waiting for and is the last one from the PAPR meeting.

The first file is his powerpoint presentation and the second is a word file containing his verbage and is set up like a paper.

Thanks !

Betty
Peak Inhalation Air Flow & Minute Volume during a Controlled Test Performed on an Ergometer

Göran Berndtsson (Author)
The S.E.A. Group
Los Angeles

Flisa Berndtsson, Sara Jessup, Tara McNamara (Assistance and Data Collection)
The S.E.A. Group
Sydney, Australia

Introduction
This study was performed by The SEA Group at their Human Subject Test Laboratories in Sydney, Australia. Five negative pressure full face mask respirators and one positive pressure demand powered air purifying respirator (PPDPAPR) were used in this test.

The results of this test emphasize that we at present do not test respiratory protective devices (RPD) adequacy to ensure that the user can use the RPD without undue physiological burden (breathing resistance), nor can we with confidence ascertain that the RPD will actually offer the protection the user expects or should be entitled to get from a product which is certified and/or deemed to comply with NIOSH, CE or Australia/NZ standards.

Conclusions and Recommendations

1. Inspiratory air flow rates are high for all exercises. This concurs with earlier findings by the author as well as by Dr. J. Kaufman, Respiratory Airflow in Working Individuals Wearing Chemical Protection, Professor I. Holmér, Respiratory flow patterns during physical work with respirators, and Dr. P-O. Åstrand, Textbook of Work Physiology.

2. The work which best represent a first responder’s typical work (150 Watt external work) generates high PIAF rates, all in excess of the typical test flows, raising the question, how well will the first responder be protected if we don’t test at a typical flow rate for this type of work?

3. At 150 Watts external work, a full 90% of the inhalation sequence is made up of air that flows faster than 115 lit/min without speech. A whole 42% flows faster than 200 lit/min.

4. In order to maintain positive pressure for 95% of all first responders, an air flow of 367 lit/min is required (this is based on flows measured in negative pressure full face masks).

Based on this data and data collected and presented by Dr. J. Kaufman, (Respiratory Airflow in Working Individuals Wearing Chemical Protection), and Professor I. Holmér, (Respiratory flow patterns during physical work with respirators) as well as what’s published in all modern text books in Physiology in particular Sport Physiology I propose the following recommendations for the New Standards for RPD for use by First Responders and other who need protection in CBRN situations.

1. To maintain the level of protection required when exposed to hazards typically classified as CBRN compound’s, we need a performance level which will assure that a so called Positive Pressure respirator really maintain Positive Pressure. Based on the Data collected and presented recently ("Peak Inhalation Air Flow during an Agility Test Performed by the US Marine Corps"), and if we want to protect the 95% tale, then we need RPD’s to maintain Positive Pressure at 427 lit/min.

2. The RPD shall have an alarm to warn the user when Positive Pressure can no longer be maintained during a substantial portion of the inhalation cycle (filter clogged, battery voltage low or work rate to high).
Background

The inhaled air passes through a filter or filters, a fan unit and/or a face mask, and then to the lungs of the wearer. Any respirator being of the positive pressure demand or negative pressure type needs to be carefully fitted to minimize the risk of face seal leakage, so only filtered air is distributed to the lungs, where the oxygen will be extracted into the bloodstream.

One identified limitation is the capability to maintain a sufficient amount of supplied air to the user by equipment such as PAPRs and the so-called positive pressure respirators which are tested and approved to existing standards.

This study was designed to simulate different work intensities which are common when workers are required to wear RPD when performing their assigned tasks. We decided to use an ergometer (test bicycle) to simulate the different workloads; most people would be comfortable riding a bicycle.

NOTE: To avoid misunderstandings, the term \textit{liters/minute} is used when referring to PIAF (Peak Inhalation Air Flow) and \textit{minute liters} when referring to volume of air.

Material and methods

The equipment used comprised five negative pressure full face masks and a [PPD]-FPBR ([Positive Pressure Demand]-Fan-supplied Positive pressure Breath Responsive Respirator) model SE400AT (listed below); the aim was to get a range of both inhalation and exhalation resistance.

A silicone full face mask with two exhalation valves and only the filter used for the flow measurement was used for low resistance with a pressure drop of -0.4 millibar at 85 liters/minute for inhalation and a pressure drop of +0.14 millibar at 85 liters/minute exhalation.

The second RPE was an SEA full face mask with a NIOSH-approved (National Institute for Occupational Safety and Health) DP (Domestic Preparedness) filter plus the flow meter with a pressure drop of -2.8 millibar at 85 liters/minute for inhalation and a pressure drop of +0.9 millibar at 85 liters/minute exhalation.

The third RPE was an M40 with a US NBC military filter and the flow meter with a pressure drop of -2.81 millibar at 85 liters/minute for inhalation and a pressure drop of +1.87 millibar at 85 liter/minute exhalation.

The fourth RPE was an SEA SE400 respirator. We used only the flow meter, as the filter as the performance of equipment is independent of the pressure drop over the filter, with a pressure drop of +1.875 at 85 liters/minute for inhalation and a pressure drop of +2.45 millibar at 85 liter/minute min exhalation.

The fifth RPE was a silicone full face mask with two exhalation valves, the filter used for the flow measurement was an A1P3 (organic vapor and particulate P100) with a resistance pressure drop of -0.66 millibar at 85 liters/minute for inhalation and a pressure drop of +0.14 millibar at 85 liters/minute exhalation.

The sixth RPE was a SEA SMF of Halo Butyl material with side-mounted filter, one exhalation valve, with a DP filter (Domestic Preparedness) with a resistance pressure drop of -2.9 millibar at 85 liters/minute for inhalation and a pressure drop of +0.23 millibar at 85 liters/minute exhalation.

The graph below shows the pressure drop for inhalation and exhalation flows up to 600 lit/min.
Test equipment used

Using a Monark 839E Ergomedic Test Bike connected to a computer, a test protocol was developed using the software supplied with the test bike.

We started at a work rate of 50 W (Watts), increasing the rate every five minutes by 25 W and stopping after 40 min or when the test subject reached 85% of the theoretical maximum heart rate (227 minus the subject’s age for women or 220 minus the subject's age for men multiplied by 0.85).

The test was also discontinued if the %SpO₂ (percent oxygen saturation) went below 92% or if the subject felt distress.

The heart rate was measured using POLAR S610 heart rate monitors, downloading to POLAR software.

We measured %SpO₂ using an Onyx 9500 Finger Pulse Oxymeter.

The volume of air breathed through the respirator (VO) was measured, as well as PIAF (Peak Inhalation Air Flow) using a flow/volume meter based on pressure-drop change over a known resistance. These meters are very fast, recording at 50Hz, which gives an outstanding resolution and makes it possible to record the very fast changes that occur when inhaling in conjunction with speech (see appendix 2).

When measuring PIAF, a flow meter based on pressure drop is a good choice, as it is as fast as required (necessary to measure liters per millisecond).

The pressure drop over the resistance is not linear. The discrepancy between the true flow and the measured flow is described in the table below (Table 1).
For this test, we chose a simple solution: we calibrated the flow meter at 200 liters, as we expected this to be in the area where we would see most information.

Conditions in the test room: temperature 23 ±3 degrees Celsius and humidity 47% ±5%.

All data has been recalculated back to STPD (Standard Temperature Pressure Dry) for ease of comparison with other data.

The heart rate was measured with Polar Electro heart rate meter (S610).

Subjects

Ten test subjects (8 male and 2 female) participated in the study. Anthropometric details are given in table 2.

Test Procedures

The test was carried out by The SEA Group, at their Human Subject Test Laboratories in Sydney, Australia.

The subjects were dressed in gym clothing (shorts, t-shirts and sneakers).

An introduction to the reason for the test and an opportunity to get familiar with the different test masks were given before the test.

The protocol was as follows:

The test was divided in to eight five-minute sections, each with different external workload, starting at 50 Watts external workload, increasing by 25 Watts every 5 minutes. This resulted in the highest section being 225 Watts external workload.

Within each section, during the first three minutes, the test subject could pedal the bike with no interference. This allowed the subject’s heart rate and breathing pattern to equalize.

During the fourth minute, the test subject was required to read aloud as when talking normal. We used the text applied in testing RPEs, i.e. The Raindrop sentence; “When the sunlight strikes raindrops in the air […]”. This reading was repeated for one minute.

During the fifth minute, the subject pedaled before the program automatically increased the resistance by 25 W. The sequence was then repeated, over and over again, until we reached either forty minutes or 85% of max heart rate.

(See test program appendix 1.)
Results (this report includes the data for the first five work load sections 50 Watts to 150 Watts)

As has been written by many authors\(^6\) of research before me, the result clearly shows that a human can breathe very high volumes with very high PIAF's.

The spreads of both volume and PIAF were large. The average minute volume was 22.20 minute liters (when talking in the first work section) — 61.57 minute liters, and the average PIAF was 99.49 lit/min to 268.02 lit/min (with maximum PIAF reaching 533.73 lit/min )

The heart rate was linear to the workload, independent of the breathing resistance. This is what we expected. \(^1,9\)

The %SpO\(_2\) — per cent oxygen saturation in the blood — was between 99%-92%.

The reduction occurred in particular when a RPE with high pressure drop was used at a higher work load and while speaking.

These factors interfere with the breathing frequencies to such a degree that %SpO\(_2\) decreased.

This is what Silverman concluded in his research.\(^8,9,10\) The implication of this should be investigated more (see attached appendix 3 Oxygen Consumption and Delivery Summary by Dr B. M. Drew).

No test subject could continue to a workload of 225 W and still remain below 85% of theoretical heart rate.

The results for work level 1 (50 Watt at the test bike) this is a conclusion of 63 test results:

Average minute volume at the third minute 26.39 minute liter with an average PIAF of 101.4 lit/min.

The fourth minute including speech the volume dropped to 22.20 minute liters; this is a drop of 16% for the volume. The PIAF increased to an average of 177.86 lit/min, an increase of 75% over the PIAF before speech.

In the fifth minute, the recovery minute before workload increased by 25 Watt, the volume rose to 30.10 minute liter — an increase of 14% compared with the minute just before speech.

This pattern was consistent all through the test. As the workload increases and the test subjects get closer to their theoretical maximum, the difference between average PIAF with and without speech becomes smaller.

Below is a sample of a typical graph of 30 minutes test with one of the test subjects.
Data

The importance of PIAF (Peak Inhalation Air Flow)

If the PIAF is higher than the supply capability of the PAPR, the performance protection of the PAPR is not higher than its face mask as a negative pressure respirator — in this case a full face mask — and what influences the performance is the capability to seal against the face at all different pressure drops.

The performance of the filters also plays a role at this high PIAF. As mentioned earlier, the particulate part of the filter is influenced by the velocity of the air moving through it.

It is commonly accepted that a gas filter's capacity against organic compounds is not significantly influenced by higher air flow (pulsating flow has been verified by NIOSH). The performance against acid and ammonia has yet to be verified at higher flow (pulsating flow).

As shown in Table 3, the average PIAF for (Low External Work Load 50 Watt) is 131.25 lit/min with a Maximum of 402.13 lit/min.

Graph 1

Frequency of distribution PIAF 50 Watts

This shows a typical distribution curve. 34% of the peak flows ranges from 100 to 150 lit/min. The 95th percentile is 232.09 lit/min at an external work load of 50 Watts, which means that in order to maintain positive pressure all the time for 95% of the population, the PAPR must have an airflow of 232.09 lit/min (see table 5).
What does 50 Watts of external work represent?

**Sitting at ease:** light manual work (writing, typing, drawing, sewing, book-keeping); **hand and arm work** (small bench tools, inspection, assembly or sorting of light material); **arm and leg work** (driving vehicle in normal conditions, operating foot switch or pedal).

**Standing:** drill (small parts); milling machine (small parts); coil winding; small armature winding; machining with low power tools;

**Casual walking:** (speed up to 3.5 km/h or 2.2 mph).

This is not hard work and possibly not representative for the first responders, so lets have a lock on work load more representative for this user group.

**A more appropriate work level** would possibly be what we in the new ISO working group refer to as Very High Work Load (ISO 8996:1990 Annex A Very High Metabolic rate of 520Watt)

This translates to approximately 150 Watt external work. We can describe this as: **Very intense activity at fast to maximum pace:** working with an axe; intense shovelling or digging; climbing stairs, ramp or ladder; walking quickly with small steps, running, or **walking at a speed** greater than 7 km/h or 4.4 mph.

This work is more applicable to a first responder, for instance, who needs a respirator for CBRN protection.

As shown in Table 6, the average PIAF for Very High External Work Load (150 Watt) is 268.02 lit/min with a Max of 533.73 lit/min.

<table>

Graph 2

**Frequency of distribution PIAF 150 Watts**

Conclusions:

- Inspiratory air flow rates are high for all exercises. This concurs with earlier findings by the author as well as by Dr. J. Kaufman, Respiratory Airflow in Working Individuals Wearing Chemical Protection, Mr. I. Holmér, Respiratory flow patterns during physical work with respirators, and Dr. P-O. Ästrand, Textbook of Work Physiology.

- The work which best represent a first responder’s typical work (150 Watt external work) generates high PIAF rates, all in excess of the typical test flows, raising the question, how well will the first responder be protected if we don’t test at a typical flow rate for this type of work?

- At 150 Watts external work, a full 90% of the inhalation sequence is made up of air that flows faster than 115 lit/min without speech. A whole 42% flows faster than 200 lit/min.

- In order to maintain positive pressure for 95% of all first responders, an air flow of 367 lit/min is required.
Future work:

The test outlined here forms part of a wider spectrum of respirator research, and further work is in progress.

This should serve to give us a broader picture of the relationship between work rate, breathing resistance and PIAF in people of all ages and fitness levels.

</table>
SEA PORTABLE BREATHING RECORDING EQUIPMENT

SEA has various types of computer-based equipment to measure and record breathing curves.

At the 2000 ISRP conference in Sydney, a simple portable device was created to show human breathing accurately, displaying a curve tracking the breathing volume in real-time, using any respirator.

The device comprised a simple pressure transducer and a particle filter, and was built on the following principle: if the resistance and the pressure drop across the resistance are known, the flow rate through the resistance can be calculated.

The device was built with the aim to minimize air turbulence etc. to give as accurate a reading as possible.

With modern computers there is no need to calculate the values. Instead, simple programming can convert the raw data to the desired format using calibration points.

The device is meant to clearly show all parts of the breathing curve such as the different faces of inhalation, rest, and exhalation and not just record the peak value. To achieve this, the device records the data at a rate of fifty (50) samples per second.

The device is then calibrated or, more precisely, the software is given a raw data reading, and given the parameter that "this is the flow of x".

The respirator is fitted to a "head" connected to an air pump and a calibrated mechanical flow meter to record the airflow for continuing airflow at the calibration points.

For a final test the respirator is fitted to a calibrated breathing machine and the graphs produced are compared to the graphs from the breathing machine.

The end result is a detailed breathing curve, not to be confused with the "industry" breathing curve.

The accuracy is gained from two main factors:

- The timing of the events is set to fifty times per second. This frequency produces a nice curve and a reasonable collection of data. At first, samples where collected at a rate of 300 per second, but no degradation was seen for the lower value and a significant saving was made in terms of data storage.
- The actual flow value is shown. The original request was for a "show and tell" at the Sydney conference; hence an accuracy of ±15% was seen as sufficient in the range of 100 to 400 liters.

The equipment has since been used much more and has been given a higher profile than was originally expected.

It could have been relatively simple to improve on the accuracy, but in order to be able to mix historic data with new data and to use statistics from many different occasions, it was decided to keep the settings fixed.

As the data recorded is only changed in a linear fashion and as the calibration error is known, a simple correction curve can be used if so desired.
It should be noted that the original display was limited at 550 liters. However, all subsequent use has been of the raw data in other SEA programs.

The data recorded is highly accurate; the turbulence in the mechanical air flow meter used for calibration is the weak point, causing fluctuations in the gauge.

In summary, the corrected curve is as accurate as the calibrated mechanical flow meter used for calibration, the difference being that only steady flows can be measured, whereas the SEA device can measure dynamically changing flows.

Finally, all SEA test equipment (including mechanical and computer-driven equipment) is highly accurate and carries calibration labels and is subjected to quality control. This specific device is not, however, but is still as accurate as the equipment used to calibrate, and the calibration is regularly checked.

Please note:

- The recorded/corrected volume referred to in the graph is actually the flow rate measured in liters per minute and not volume.
- The recording is of flow and time only. Other programs, such as the SEA EDL, are used to calculate volume, number of breaths, etc.

Oxygen Consumption and Delivery

Summary

Dr Billy Markus Drew MBBS
3/16 Whiting Ave
Terrigal, NSW 2260
AUSTRALIA
Oxygen Consumption and Delivery

Consumption

- Resting oxygen consumption is 250 mls/min
- This increases up to 4000 mls/min in heavy exercise to enable aerobic metabolism of body’s stored fuels.
- Aerobic metabolism (using O₂) is a far more efficient way to use stored fuel (simplistically about 18 times in the initial conversion phase) than burning fuel anaerobically (without O₂)

Delivery

- O₂ delivery to the tissues is dependent on the oxygen flux equation
  - Delivery O₂ (ml O₂/min) = Cardiac Output (100 mls/min) x [haemoglobin concentration (g/100ml) x saturation of O₂ (%) x 1.34 (ml/g) + partial pressure of O₂ (mmHg) x 0.003 (ml/100ml/mmHg)]
  - Each gram fully saturated haemoglobin contains 1.34 mls of O₂ (4 molecules)
  - Normal haemoglobin=15g/100ml : 1.34ml/g x 15g/100ml = 20.1ml O₂/100ml blood (if 100% saturated)
  - Dissolved O₂ is linear = 0.003 ml/100ml/mmHg PO₂ (negligible in terms of content of O₂ compared to haemoglobin)
  - Not all blood goes through the lungs (physiological shunt) therefore arterial blood is usually 97% saturated (strangely enough is equal to PO₂ 97 mmHg)
    - : 20.1x97/100 +0.003x97 = 19.8 mls O₂ / 100ml blood
    - At rest if cardiac output = 5 L/min → O₂ delivery = 990 mls O₂/min (lungs to tissues)
  - This is about four times resting O₂ consumption
  - THUS, equation can be simplified to
    - DO₂ = CO x Hb x SO₂ x 1.34
  - What does all this mean?

The delivery of oxygen to the tissues is dependent on cardiac output which is normally 5 l/min but can increase to 25 l/min in severe exercise (i.e. 5 times)

- It is also dependent on the haemoglobin concentration. This can be considered constant in everyday people but women usually have slightly less than men.
- Finally, it is dependent on the saturation. This is dependent on the minute ventilation (l/min ventilated through lungs) and the inspired oxygen concentration (air has 21% oxygen). To a lesser degree, it is also dependent on cardiac output. Usually each blood cell takes 0.75 seconds to pass through the lung capillary but when the cardiac output is very high, such as during severe exercise, the red blood cell has less time in the lung capillary and therefore has less time for the oxygen to attach to the haemoglobin molecule.

Oxygen Saturations

- Diffusion of oxygen depends on the partial pressure gradient of O₂ between the blood and tissues
  - The relationship between oxygen content and partial pressure is via the oxy-haemoglobin dissociation curve
Figure 35-2. Oxygen-hemoglobin dissociation curve. 
PH 7.40, temperature 38 °C.

- This is a sigmoid curve – a normal arterial saturation is about 97%
- Venous blood saturations are about 75%
- Thus, in the lungs a big change in partial pressure of oxygen does not affect the saturation that much but at a tissue level a small change in PO2 is associated with a more unloading of O2 for use by muscles etc
- In strenuous exercise it should be noted that the above curve can shift to the right to increase oxygen extraction up to 3 times

- What does a drop in O2 saturations mean?
  - In simplistic terms, saturations reflect O2 content and is dependant on a balance between consumption and uptake, so when consumption is greater than uptake (very heavy exercise) we will see a drop in saturations. A drop in O2 delivery to the muscles means they must revert to the inefficient anaerobic fuel pathways, lactic acidosis will occur and fatigue will develop.

What PIAF do we need to assure Positive Pressure for 95% of the First Responders

NIOSH Multifunction PAPR CBRN Standard meeting April 10 2003
Introduction:
The results of this test emphasize that we at present do not test respiratory protective devices (RPD) adequacy to ensure that the user can use the RPD without undue physiological burden (breathing resistance), nor can we with confidence ascertain that the RPD will actually offer the protection the user expects or should be entitled to get from a product which is certified and/or deemed to comply with NIOSH, CE or Australia/NZ standards.
The Study!

- This study was designed to simulate different work intensities which are common when workers are required to wear RPD when performing their assigned tasks. We decided to use an ergometer (test bicycle) to simulate the different workloads; most people would be comfortable riding a bicycle.
Material and methods

- The equipment used comprised five negative pressure full face masks and a PPD-FPBR ([Positive Pressure Demand]-Fan-supplied Positive pressure Breath Responsive Respirator) model SE400AT.
Pressure Drop in millibar per liter/minute flow
Subjects

Ten test subjects (8 male and 2 female) participated in the study.

Average All Subjects
The protocol was as follows:

- The test was divided into eight five-minute sections, each with different external workload, starting at 50 Watts external workload, increasing by 25 Watts every 5 minutes. This resulted in the highest section being 225 Watts external workload.
Within each section, during the first three minutes, the test subject could pedal the bike with no interference. This allowed the subject's heart rate and breathing pattern to equalize.

During the fourth minute, the test subject was required to read aloud as when talking RPEs, i.e. The Raindrop sentence; "When the sunlight strikes raindrops in the air [...]"

This reading was repeated for one minute. During the fifth minute, the subject pedaled before the program automatically increased the resistance by 25 W. The sequence was then repeated, over and over again, until we reached either forty minutes or 85% of max heart rate.
Results

- The spreads of both volume and PIAF were large.
- The average minute volume was 22.20 minute liters (when talking in the first work section) — 61.57 minute liters, and the average PIAF was 99.49 lit/min to 268.02 lit/min (with maximum PIAF reaching 533.73 lit/min).
The results for work level 1

- Average minute volume at the third minute 26.39 minute liter with an average PIAF of 101.4 lit/min.
The results for work level 1

- The fourth minute including speech the volume dropped to 22.20 minute liters; this is a drop of 16% for the volume. The PIAF increased to an average of 177.86 lit/min, an increase of 75% over the PIAF before speech.
The results for work level 1

- In the fifth minute, the recovery minute before workload increased by 25 Watt, the volume rose to 30.10 minute liter — an increase of 14% compared with the minute just before speech.
The Green line represents 86 lit/min., the test flow for NOSH. As we can see here the total volume breath by this 49 year old test subject where 1476 liter of air, of this 1296.7 liter or 88% of the total volume where flowing faster than 85 lit/min. This is a serious problem in particular when it comes to Particle filters as they are velocity dependent.

This is the period when the test subject are reading. As we can see the PIAF changed dramatically with talking.
### Low External Work Load

**50 Watt**

What does 50 Watts of external work represent?

- Sitting at ease: light manual work (writing, typing, drawing, sewing, book-keeping); hand and arm work (small bench tools, inspection, assembly or sorting of light material); arm and leg work (driving vehicle in normal conditions, operating foot switch or pedal).
- Standing: drill (small parts); coil winding; small armature winding; machining with low power tools.
- Casual walking: (speed up to 3.5 km/h or 2.2 mph).
Is this representative for a First Responder?

- This is not hard work and possibly not representative for the first responders, so let's have a lock on work load more representative for this user group.
Is this representative for a First Responder?

- A more appropriate work level would possibly be what we in the new ISO working group refer to as Very High Work Load (ISO 8996:1990 Annex A Very High Metabolic rate of 520 Watt)
Very High Work Level 150 Watt

External Work

- This translates to approximately 150 Watt external work. We can describe this as:

- Very intense activity at fast to maximum pace; working with an axe; intense shovelling or digging; climbing stairs, ramp or ladder; walking quickly with small steps, running, or walking at a speed greater than 7 km/h or 4.4 mph.
Very High Work Level 150 Watt External Work

- This work is more applicable to a first responder, for instance, who needs a respirator for CBRN protection.

Conclusions:

- Inspiratory air flow rates are high for all exercises. This concurs with earlier findings by the author as well as by Dr. J. Kaufman, Respiratory Airflow in Working Individuals Wearing Chemical Protection, Mr. I. Holmér, Respiratory flow patterns during physical work with respirators, and Dr. P-O. Åstrand, Textbook of Work Physiology.
Conclusions:

- The work which best represents a first responder's typical work (150 Watt external work) generates high PIAF rates, all in excess of the typical test flows, raising the question, how well will the first responder be protected if we don't test at a typical flow rate for this type of work?
Conclusions:

- At 150 Watts external work, a full 90% of the inhalation sequence is made up of air that flows faster than 115 lit/min without speech. A whole 42% flows faster than 200 lit/min.
Conclusions:

Lit/min is required.

Responders, an air flow of 427
pressure for 95% of all first
order to maintain positive
Recommendations

Based on this data and data collected and presented by Dr. J. Kaufman, (Respiratory Airflow in Working Individuals Wearing Chemical Protection), and Professor I. Holmér, (Respiratory flow patterns during physical work with respirators) as well as what’s published in all modern text books in Physiology in particular Sport Physiology. I propose the following recommendations for the New Standards for RPD for use by First Responders and others who need protection in CBRN situations.
Recommendations

To maintain the level of protection required when exposed to hazards typically classified as CBRN compounds, we need a performance level which will assure that a so-called Positive Pressure respirator really maintain Positive Pressure. Based on the Data collected and presented recently \("\text{Peak Inhalation Air Flow during an Agility Test Performed by the US Marine Corps}\), and if we want to protect the 95% tale, then we need RPD's to maintain Positive Pressure at 427 lit/min.
Recommendations

- The RPD shall have an alarm to warn the user when Positive Pressure can no longer be maintained during a substantial portion of the inhalation cycle (filter clogged, battery voltage low or work rate too high).
Thank you for your attention.
